Fuhrman & Zimmerman's Pediatric Critical Care

FIFTH EDITION

BRADLEY P. FUHRMAN, MD, FCCM

Professor and Chair, Department of Pediatrics, Texas Tech University – Paul L. Foster School of Medicine, Physician-in-Chief, El Paso Children's Hospital, El Paso, Texas

JERRY J. ZIMMERMAN, MD, PhD, FCCM

Professor of Pediatrics and Anesthesiology, Faculty, Pediatric Critical Care Medicine, Seattle Children's Hospital, Harborview Medical Center, University of Washington School of Medicine, Seattle, Washington

Robert S.B. Clark, MD

Professor and Chief, Pediatric Critical Care Medicine, Medical Director, Brain Care Institute, Children's Hospital of Pittsburgh of UPMC, Associate Director, Safar Center for Resuscitation Research, University of Pittsburgh, School of Medicine, Pittsburgh, Pennsylvania

Monica Relvas, MD, FAAP, FCCM, MSHA

Medical Director, Pediatric Critical Care Medicine, Covenant Women and Children's Hospital, Associate Clinical Professor, Texas Tech University, Lubbock, Texas

Alexandre T. Rotta, MD, FCCM

Linsalata Family Chair in Pediatric Critical Care and Emergency Medicine, Chief, Division of Pediatric Critical Care Medicine, UH Rainbow Babies and Children's Hospital, Professor, Department of Pediatrics, Case Western Reserve University School of Medicine, Cleveland, Ohio

Ann E. Thompson, MD, MHCPM

Professor, Critical Care Medicine, Vice Dean, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Joseph D. Tobias, MD

Chief, Department of Anesthesiology and Pain Medicine, Nationwide Children's Hospital, Professor of Anesthesiology and Pediatrics, The Ohio State University, Columbus, Ohio

PEDIATRIC CRITICAL CARE, FIFTH EDITION
ISBN: 978-0-323-37839-0

Previous editions copyrighted 2011, 2006, 1998, 1992.

Library of Congress Cataloging-in-Publication Data

Names: Fuhrman, Bradley P., editor.
Title: Pediatric critical care / [edited by] Bradley P. Fuhrman, Jerry J. Zimmerman, Joseph A. Carcillo, Robert S.B. Clark, Monica Relvas, Alexandre T. Rotta, Ann E. Thompson, Joseph D. Tobias.
Other titles: Pediatric critical care (Fuhrman)
Description: Fifth edition. | Philadelphia, PA : Elsevier, [2017] | Includes bibliographical references and index.
Identifiers: LCCN 2016034617 | ISBN 9780323378390 (hardcover : alk. paper)
Subjects: | MESH: Critical Care | Child | Infant
Classification: LCC RJ370 | NLM WS 366 | DDC 618.92/0028—dc23 LC record available at https://lccn.loc.gov/2016034617

Legends for Cover Figures:

Figures from left to right:
Schematic depiction of gram-negative bacteremia.
Schematic depiction of Toll-like receptor 4, an element of innate immunity that binds lipopolysaccharide of the gram-negative cell wall (endotoxin), initiating a cascade of intracellular signaling to promote a proinflammatory host response.
Host mRNA expression of the most affected genes in a child with bacterial sepsis. Red, upregulation; blue, downregulation. Courtesy, Hector Wong.
Alterations in microvascular flow and effective capillary density of the buccal mucosa using orthogonal polarization spectral imaging in a patient with bacterial sepsis.

Clinical Assistant Professor
Pediatric Critical Care
Seattle Children's Hospital/University of Washington
Seattle, Washington

David Jardine MD
Associate Professor
Department of Otolaryngology
Seattle Children's Hospital/University of Washington School of Medicine
Seattle, Washington

Alberto Jarillo MD
Head
Respiratory Therapy Service
Associate Professor of Pediatric
Critical Care and Pediatrics
Hospital Infantil de Mexico Federico Gomez
Mexico City, Mexico

Alison M. Jeziorski MD, MBA
Assistant Professor
Department of Anesthesia and Perioperative Medicine
Medical University of South Carolina
Charleston, South Carolina

Umesh Joashi MD
Consultant Paediatric Intensivist
Leeds Teaching Hospitals NHS Trust
Leeds, United Kingdom

Prashant Joshi MD
Associate Professor
Pediatrics
University of Nebraska Medical Center
Omaha, Nebraska

Richard J. Kagan MD
Professor

Surgery
University of Cincinnati College of Medicine
Cincinnati, Ohio

Prince J. Kannankeril MD
Associate Professor
Pediatrics
Vanderbilt Children's Hospital
Nashville, Tennessee

Robert K. Kanter MD †
Adjunct Senior Research Scientist
National Center for Disaster Preparedness
Columbia University
New York, New York

Oliver Karam MD
Associate Professor
Pediatric Intensive Care Unit
Geneva University Hospital
Geneva, Switzerland

Cristin D.W. Kaspar MD
Pediatric Nephrology Fellow
Children's Hospital of Richmond
Virginia Commonwealth University School of Medicine
Richmond, Virginia

Robinder G. Khemani MD, MsCI
Associate Director of Research
Department of Anesthesiology and Critical Care
Critical Care Medicine
Children's Hospital Los Angeles
Associate Professor of Pediatrics
University of Southern California Keck School of Medicine
Los Angeles, California

Mary A. King MD
Professor of Genome Sciences and of Medicine
University of Washington
Seattle, Washington

Christa C. Jefferis Kirk PharmD
Clinical Staff Pharmacist
Critical Care
Seattle Children's Hospital
Seattle, Washington

Niranjan (Tex) Kissoon MD

Professor in Acute and Critical Care—Global Child Health
Pediatrics and Surgery (EM)
The University of British Columbia and BC Children's Hospital
Vancouver, British Columbia, Canada

Patrick M. Kochanek MD, MCCM
Ake N. Grenvik Professor and Vice Chair of Critical Care Medicine
Professor of Anesthesiology, Pediatrics and Bioengineering, and Clinical and Translational Science
Director
Safar Center for Resuscitation Research
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Keith C. Kocis MD, MS
Director
Pediatric Cardiac Intensive Care
Interim Director
Pediatric Critical Care Medicine
Sidra Medical and Research Center
Doha, Qatar

Samuel A. Kocoshis MD
Professor
Pediatrics
University of Cincinnati College of Medicine
Cincinnati, Ohio

Tsingyi Koh PharmD, BCPS
Principal Clinical Pharmacist Pediatrics/Solid Organ Transplant
Department of Pharmacy
National University Hospital
Singapore

Ada Kong PharmD
Research Pharmacist
Seattle Children's Hospital/University of Washington
Seattle, Washington

Ildiko H. Koves MD, FRACP
Associate Professor
Endocrinology and Diabetes
Seattle Children's Hospital/University of Washington
Seattle, Washington

Thomas J. Kulik MD
Senior Associate in Cardiology
Cardiology
Boston Children's Hospital

Boston, Massachusetts

Vasanth H. Kumar MD
Associate Professor
Department of Pediatrics
Director
Neonatal-Perinatal Medicine Fellowship Program
The State University of New York at Buffalo
Women and Children's Hospital of Buffalo
Buffalo, New York

Jacques Lacroix MD
Professor
Division of Pediatric Intensive Care
Department of Pediatrics
Sainte-Justine Hospital
Université de Montréal
Montreal, Quebec, Canada

Satyan Lakshminrusimha MD
Professor of Pediatrics
Chief
Division of Neonatology
Women and Children's Hospital of Buffalo
Director
Center for Developmental Biology
The State University of New York at Buffalo
Buffalo, New York

Thomas J. Lee MD
Major
United States Air Force
San Antonio, Texas

Marie Leiner PhD
Research Associate Professor
Pediatrics
Texas Tech University Health Sciences Center
El Paso, Texas

Daniel L. Levin MD
Professor Emeritus
Departments of Pediatrics and Anesthesia
Children's Hospital at Dartmouth
Geisel School of Medicine
Lebanon, New Hampshire

Mithya Lewis-Newby MD, MPH
Associate Professor

Departments of Pediatrics and Bioethics and Humanities
Treuman Katz Center for Pediatric Bioethics
Seattle Children's Hospital/University of Washington School of Medicine
Seattle, Washington

Mary W. Lieh-Lai MD, FAAP, FCCP
Senior Vice President for Medical Accreditation
Accreditation Council for Graduate Medical Education
Professor of Pediatrics (Vol)
Wayne State University School of Medicine
Chicago, Illinois

Catherine Litalien MD, FRCPC
Associate Professor
Division of Pediatric Intensive Care
Department of Pediatrics
Director
Clinical Pharmacology Unit
CHU Sainte-Justine
Université de Montréal
Montreal, Quebec, Canada

Alejandro Lopez-Magallon MD
Assistant Professor
Critical Care Medicine
University of Pittsburgh
Pittsburgh, Pennsylvania

Robert Lynch MD

Pediatrics
Texas Tech University—Paul L. Foster School of Medicine Health Sciences Center
El Paso, Texas

Amy T. Makley MD
Assistant Professor of Surgery
University of Cincinnati
Cincinnati, Ohio

Alfredo Maldonado MS, MD
Assistant Professor
Department of Pediatrics
Division of Pediatric Emergency Medicine
Texas Tech University Health Sciences Center
El Paso, Texas

Barry Markovitz MD
Professor
Anesthesiology and Pediatrics
USC Keck School of Medicine
Los Angeles, California

Paula M. Mazur MD
Associate Clinical Professor of Pediatric Emergency Medicine and Child Abuse Pediatrics
University Pediatrics Associates
John R. Oishei Children's Hospital
Buffalo, New York

Jennifer McArthur MD
Associate Professor of Pediatrics
Pediatric Critical Care
Medical College of Wisconsin
Milwaukee, Wisconsin

Gwenn E. McLaughlin MD, MSPH, FAAP, FCCM
Professor of Clinical Pediatrics
Division of Pediatric Critical Care Medicine
University of Miami Miller School of Medicine
Attending Physician
Miami, Florida

Susan F. McLean MD, FACS
Associate Professor of Surgery
Texas Tech University Health Sciences Center El Paso
Surgical Intensive Care Unit Director and Associate Trauma Medical Director
University Medical Center of El Paso
El Paso, Texas

Nilesh M. Mehta MD
Associate Professor of Anesthesia
Harvard Medical School
Senior Associate
Director of Critical Care Nutrition
Department of Anesthesiology, Perioperative and Pain Medicine
Boston Children's Hospital
Boston, Massachusetts

Renuka Mehta MS
Medical College of Georgia Medical Center
Augusta, Georgia

Ann J. Melvin MD
Associate Professor
Pediatric Infectious Diseases
Seattle Children's Hospital/University of Washington School of Medicine
Seattle, Washington

Ayesa N. Mian MD
Pediatric Nephrology
University of Rochester School of Medicine
Rochester, New York

Rohit Mittal MD
Research Resident
Emory University
Atlanta, Georgia

Patricia A. Moloney-Harmon RN, MS, CCNS, CCRN, FAAN
Clinical Nurse Specialist
Children's Services
Sinai Hospital
Baltimore, Maryland

Paul Monagle MBBS, MD, MSC
Professor
Stevenson Chair
Head of Department
Paediatrics
University of Melbourne
Melbourne, Victoria, Australia

Chet Moorthy MD
Medical Director of Radiology
El Paso Children's Hospital
El Paso, Texas

Wynne Morrison MD, MBE
Assistant Professor
Department of Anesthesiology and Critical Care
Director
Pediatric Advanced Care Team
The Children's Hospital of Philadelphia
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania

Ricardo Munoz MD

Chief
Pediatric Cardiac Critical Care
Children's Hospital of Pittsburgh of UPMC
Pittsburgh, Pennsylvania

Raj Munshi MD
Nephrology
Seattle Children's Hospital/University of Washington
Seattle, Washington

Srinivas Murthy MD
Assistant Professor of Critical Care
Pediatrics
BC Children's Hospital
University of British Columbia
Vancouver, British Columbia, Canada

Jennifer A. Muszynski MD
Assistant Professor of Pediatrics
Division of Critical Care Medicine
Department of Pediatrics
Nationwide Children's Hospital
The Ohio State University College of Medicine
Columbus, Ohio

Vinay M. Nadkarni MD, MS
Endowed Chair
Pediatric Critical Care Medicine
Professor of Anesthesiology
Critical Care and Pediatrics
The Children's Hospital of Philadelphia
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania

Thomas A. Nakagawa MD
Professor and Section Head
Pediatric Critical Care Medicine
Anesthesiology and Pediatrics
Wake Forest School of Medicine
Winston-Salem, North Carolina

Navyn Naran MD, Niagara Falls, Ontario, Canada

Tara M. Neumayr MD
Instructor of Pediatrics
Division of Pediatric Critical Care Medicine
Washington University School of Medicine
St. Louis, Missouri

Akira Nishisaki MD, MSCE
The Children's Hospital of Philadelphia
Department of Anesthesiology and Critical Care Medicine
Philadelphia, Pennsylvania

Victoria F. Norwood MD
Robert J. Roberts Professor of Pediatrics
Chief of Pediatric Nephrology
University of Virginia
Charlottesville, Virginia

Daniel A. Notterman MA, MD, FAAP, FCCM
Professor
Department of Molecular Biology
Princeton University
Princeton, New Jersey
Clinical Professor of Pediatrics
Rutgers—Robert Wood Johnson Medical School
New Brunswick, New Jersey

Alan W. Nugent MBBS
Associate Professor
Pediatrics
University of Texas Southwestern Medical Center
Director
Cardiac Catheterization
Children's Medical Center
Dallas, Texas

Peter Oishi MD
Associate Professor of Pediatrics
Medical Director
Pediatric Intensive Care Unit, Transport and Access, Transitional Care Unit
Director
Pediatric ECLS Program
UCSF Beinoff Children's Hospital, San Francisco
San Francisco, California

Jeffrey Ojemann MD
Division Chief of Neurosurgery
Director of Epilepsy Surgery
Co-Director
Epilepsy Program
Richard G. Ellenbogen Endowed Chair in Pediatric Neurosurgery
Seattle Children's Hospital/University of Washington College of Medicine
Seattle, Washington

Richard A. Orr MD, FCCM
Professor

Critical Care Medicine and Pediatrics
Staff
Cardiac Intensive Care Division
University of Pittsburgh Medical Center

Preface

Wandering through the exhibit hall of the Toronto Convention Center and the 8th World Congress of Pediatric Critical and Intensive Care Medicine, I am beginning to compose the text of these forward comments in my head. Although pediatric critical care medicine has embraced a global perspective from the beginning, the international flavor of this meeting is particularly striking. Perhaps this reflects the fact that the pediatric critical care medicine fellowship training program at the Hospital for Sick Children has always been a melting pot for trainees around the world. Poster presentations and associated rich discussions here suggest that all pediatric critical care practitioners face similar challenges. Without a doubt the fifth edition embodies the spirit of pediatric critical care medicine as I am experiencing it in person here in Toronto.

At the Elsevier booth I spot a mock-up of the fifth edition of *Pediatric Critical Care*. Even though I know that one should not judge a book by its cover, I must say, the cover looks pretty good, and moreover, I know the contents of the book are outstanding. Once again, all of the effort involved in this revision appears worthwhile. This notion is affirmed by colleagues from all over the world who take time from their busy schedules to make a point of telling me that they are anxious to receive their copy of the latest edition later this year. Meanwhile, I am aware that authors and section editors continue to review final proofs of their chapters, and Monica Relvas continues to encourage contributors to provide board review questions in the correct format. Subsequently I travel back to Chicago where Brad Fuhrman and I first met to design the first edition of *Pediatric Critical Care* in 1990. At that time, just 3 years after the first board certification exam, our field was considerably less mature than what I witness daily in the Seattle Children's Hospital intensive care units and at national and international meetings.

From the beginning, pediatric critical care medicine has embraced the concept of multidisciplinary care including engagement of the family in the care plan, but brief review of the contents of Section I of the fifth edition documents how far we have come. The vision espoused by the Institute for Patient and Family Centered Care—engagement of patients and families in the critical care plan—took shape around the same time as the first edition of this textbook. Neonatal and pediatric intensive care units were understandably early adaptors of this philosophy. Now, multiinstitutional quality improvement initiatives like ICU Liberation and the Patient-Centered Outcomes Research-Intensive Care Unit Collaborative endeavor to enhance family engagement, not because of some ethical imperative but because this practice improves clinically meaningful, long-term outcomes. In order to maximize

the benefits of family engagement, the patient must be awake enough to participate. Accordingly, the evolved approach to analgesia and anxiolysis now focuses on comfort and pain control while minimizing sedation.

Basic research scientists in translational collaboration with bedside critical care providers have enhanced our understanding of organs, cells, molecular biology, and now genetics with the ever-present goal of making the critically ill child whole again. Advances in our understanding of cardiovascular, pulmonary, neurologic, renal, gastrointestinal, metabolic, endocrine, and hematologic disorders, infectious diseases, and traumatic injury are chronicled throughout the fifth edition. Such understanding reflects a marked increase in the traditional research and quality improvement productivity of our specialty.

Two centuries ago Ignaz Semmelweis was ridiculed for his radical views on care provider handwashing. Two decades ago handwashing was regarded as important but was not regularly practiced. Today hand cleansing before and after patient contact is considered a mandatory quality measure and, as one element of a bundle of practices, validated with collaborative, multiinstitutional data, has been associated with a sustained plummet in catheter-related bloodstream infections and hospital-acquired infections in general. Like our hematology-oncology colleagues, pediatric intensivists need to develop a culture of a learning health care system, where clinical care and research are so intertwined that each cannot be separated from the other and each continuously informs the other. Every child in an intensive care unit should be a potential candidate for enrollment into a clinical investigation that ideally has been informed by translated basic research.

Although computer technology and the electronic medical record have enhanced care of our patients in many ways, an unanticipated consequence has been the movement of critical care practitioners away from the bedside and into a room with multiple computer stations. Even though modern care providers may have a wealth of information at their fingertips, if not at the bedside, the provider is missing the essence of critical care medicine: continuous titration and advancement of care, particularly weaning of support when it is no longer indicated; serial physical and ultrasonographic examinations; discussion with other care providers; sitting on the bed, holding the patient's hand, if only for a moment or two. Sir Samuel Luke Fildes captured the basic nature and quality of (critical care) medicine in his 1891 painting, *The Doctor*. It is worth taking a look to reconnect with what is ultimately the most important aspect of our specialty.

Years ago Peter Safar reminded us that critical illness begins and ends outside of the intensive care unit and hospital. Thanks in part to our neonatology colleagues and to our own success, children with chronic, comorbid conditions increasingly comprise the majority of admissions to pediatric intensive care units. As mortality associated with pediatric critical illness has steadily declined over the past several decades, critical care practitioners are acknowledging and addressing the substantial and enduring morbidity burden that many children and families surviving critical illness "take home." Almost certainly, the next large clinical interventional trial in pediatric critical care will need to examine a composite outcome measure that includes both mortality and morbidity.

With this fifth edition of *Fuhrman and Zimmerman's Pediatric Critical Care,* we are

proud to deliver a contemporary, comprehensive overview of the discipline. New and updated text, extensive figures and tables, electronic supplemental information, board review questions, and Expert Consult online all enhance the effectiveness of this latest edition. We are indebted to our families and colleagues for condoning our absence or inattentiveness to other matters, to the many dedicated authors who collaboratively have once again composed a gold standard textbook for the field of pediatric critical care medicine, and to the staff of Elsevier whose patience and expertise ultimately brought all things together.

Jerry J. Zimmerman MD, PhD

Bradley P. Fuhrman MD *Co-editors, Pediatric Critical Care*

SECTION I

Pediatric Critical Care: The Discipline

OUTLINE

CHAPTER 1

History of Pediatric Critical Care Medicine*

Daniel L. Levin, John J. Downes, I. David Todres [†]

"In critical care, it strikes one that the issues are three: realism, dignity, and love."

Jacob Javitz, 1986 (inspirational award honoree, Society of Critical Care Medicine, posthumously)

PEARLS

- The evolution of pediatric critical care medicine reflects long progress in anatomy, physiology, resuscitation and ventilation, anesthesia, anesthesiology, neonatology, pediatric general and cardiac surgery, and pediatric cardiology.
- The role of nursing is absolutely central to the evolution of critical care units.
- Until the 1950s and 1960s, intensive care units were organized by grouping patients with similar diseases, but in the 1960s neonatal intensive care units grouped children according to age and severity of illness, and pediatric intensive care units followed this example.
- Sophisticated interhospital transfer services proved significant in reducing morbidity and mortality of critically ill children starting in the1970s. This *retrieval medicine* holds great promise for future improvements in care.
- In pediatric critical care medicine there have been remarkable achievements in the ability to understand and treat critical illness in children as well as progress in the organization of pediatric critical care medicine, education, and research in the field.
- Increasing use of improved technology has advanced the care of critically ill children but has not eliminated errors, complications, or potentially long-term sequelae, and it is associated with a need for greater focus on establishing a humane, caring environment for the patients and their families.

Evolution of Modern Medicine

The evolution of pediatric critical care medicine (PCCM) reflects a long series of

contributions from anatomy, physiology, resuscitation and ventilation, anesthesia, anesthesiology, neonatology, pediatric general and cardiac surgery, pediatric cardiology and the many individuals responsible for the discoveries and innovations.[1,2] Intensive care units were originally organized by grouping together patients with the same or similar diseases but, when neonatologists grouped children according to age and severity of illness, pediatric intensive care units (PICUs) followed their example. Transport or *retrieval medicine* developed and nurses took on a major role in providing care to critically ill and injured children.

Anatomy and Physiology

What seems simple and obvious today took a great deal of time, effort, and insight to understand. This section discusses some of the contributions that advanced medicine, enabled the development of cardiorespiratory support, and, eventually, led to the establishment of intensive care.

Andreas Vesalius (1514–1564), the Flemish anatomist, corrected many previous mistakes in anatomy and provided positive pressure ventilation via a tracheotomy tube to asphyxiated fetal lambs. Michael Servetus of Spain (1511–1553) correctly described the pumping action of the heart's ventricles and the circulation of blood from the right heart through the lungs to the left heart. Unfortunately he was burned at the stake at the hands of the radical Calvinists in Geneva for his published theologic views. Matteo Realdo Columbo (1515–1559) described pulmonary circulation and the concept that the lungs added a spirituous element to the blood by the admixture of air. William Harvey (1578–1657), with his genius, published *De Motu Cordis*[3] (On the Motion of the Heart) in 1628. Because he did not yet have the microscope, he could not see the capillaries and thus could not include the mechanism for transfer of blood from the arterial to the venous system of the pulmonary circulation. Capillaries were first described by Marcello Malpighi (1628–1694, Italian) in *De Pulmonibus* (On the Lungs) in 1661. Thomas Willis (1611–1675) and, eventually, William Cullan (1710–1790) led the way to our understanding of the role of the nervous system as the site for consciousness and the regulation of vital phenomena. Richard Lower (1631–1691) proved it was the passage of blood through the lungs, ventilation of the lungs, and gas exchange with blood that vivified the blood and turned it red. Stephen Hales (1677–1761) measured blood pressure with a brass tube connected to a 9-foot glass tube in a horse. Joseph Black (1728–1799) identified carbon dioxide as a gas expired from human lungs.

Karl Wilhelm Scheele (1742–1785) isolated oxygen, as did Joseph Priestley (1733–1804), who named it dephlogisticated air and determined its vital role in supporting combustion. Antoine Laurent Lavoisier (1743–1794) identified oxygen as the vital element taken up by the lungs that maintains life and gave it its name (literally *acidgenerator*). Oxygen's essential role in physiology and biochemistry was not clarified until the late 19th century when Felix Hoppe-Seyler (1825–1895) described the transportation of oxygen in blood by hemoglobin.

Giovannni Morgagni (1682–1771) initiated the field of anatomic pathology in his classic book *De Sedibuset causis morborum per anatomen indagatis* published in 1761. He described in detail his observations of the diseased organs in more than 700 autopsies of persons with a wide variety of disorders and made correlations with the patient's appearance and symptoms, the initial clinical-pathologic basis of medicine.

In 1842 Crawford Long in Georgia and in 1846 William Morton in Boston demonstrated the efficacy and safety of ether anesthesia, thereby opening the era of modern surgery. Joseph Lister (1827–1912), one of the founders of modern surgery, reasoned that bacteria were the source of pus in rotten organic material and in 1865 used carbolic acid in surgical fields to eliminate bacteria. This technique dramatically improved patient outcomes from surgical wounds and after surgery. Along with the discovery of antibiotics, antiseptic technique was an important step in patient care. Nonetheless, imperfect antiseptic technique, sepsis, inflammation, and the consequences of multiorgan failure still represent a major portion of what pediatric intensivists deal with today. Robert Koch (1843–1910) developed his postulates in 1882 in order to attribute the etiology of a disease to a particular microorganism in a logical, scientific manner. He also identified the tubercle bacillus as the cause of tuberculosis and was awarded the Nobel Prize in 1905. Wilhelm Konrad von Röntgen (1845–1923) discovered x-rays in 1895. Scipione Riva-Rocci (1863–1937), in 1896, measured blood pressure using the sphygmomanometer, and Nikolai Korotkoff introduced his auscultation method of determining systolic and diastolic pressure in 1905.[1]

Resuscitation and Ventilatory Support

The key to understanding the present practice of intensive care for children lies in knowing the history of scientific study of cardiorespiratory anatomy and physiology and the discovery of techniques to support ill patients. Although one could think our current practice suddenly emerged with the late 20th century, technical discoveries and accomplishments in the development of resuscitation and ventilation taken for granted today date back to the Bible, and numerous events and contributions led to current practice. In a biblical story,[1,4,5] Elisha resurrected a young boy who was dead when "he climbed onto the bed and stretched himself on top of the child, putting his mouth to his mouth, his eyes to his eyes, and his hands to his hands, and as he lowered himself onto him the child's flesh grew warm. … Then the child sneezed and opened his eyes." In 117 CE, Antyllus performed tracheotomies for patients with upper airway obstruction.[6] Paracelsus, a sixteenth-century Swiss alchemist and physician, first provided artificial ventilation to both animals and dead humans using a bellows,[6] and Andreas Vesalius, a Flemish professor of anatomy, in De Humani Corporis Fabrica, reported ventilating open-chest dogs, fetal lambs, and pigs using a tracheostomy and fireplace bellows in 1543.[7-9]

The French obstetrician Desault, in 1801, described how to successfully resuscitate apneic or limp newborns by digital orotracheal intubation with a lacquered fabric tube and then blowing into the tube.[1] In 1832 Dr. John Dalziel in Scotland developed a bellows-operated intermittent negative pressure device to assist ventilation.[8] In 1864 Alfred F. Jones, of Lexington, Kentucky, built a body-enclosing tank ventilator, and in the 1880s Alexander Graham Bell developed a so-called vacuum jacket driven by hand-operated bellows.[8] In 1876 Woillez, in Paris, built what was probably the first workable iron lung, which was strikingly similar to the respirator introduced by McKhann and Drinker in 1929 and manufactured for widespread use by Emerson in 1931.[10] Braun developed an infant resuscitator, as described by Doe in 1889, which was used successfully in 50 consecutive patients. A respirator developed by Steuart in Cape Town, South Africa, in 1918 apparently successfully treated a series of polio

patients, but he did not report it.[8]

In 1888 Joseph O'Dwyer, a physician working at the New York Foundling Hospital who was concerned about the high death rate in croup and laryngeal diphtheria, instituted the manual method of blind oral laryngeal intubation using short tapered brass tubes that entered the subglottic lumen. Despite severe criticism from associates and the other practitioners, he persisted assembling a series of various diameter tubes for the palliation of severe adult and pediatric laryngeal edema due to infections, including diphtheria.

George Fell, another New York physician, devised a method of ventilation with a foot-operated bellows and exhalation valve connected by rubber tubing to the O'Dwyer tube (Fig. 1.1).[8] In 1898 Rudolph Matas of New Orleans adapted the Fell-O'Dwyer technique to perform chest wall surgery and, in the early 1900s, George Morris Dorrance of Philadelphia used the technique to perform resuscitations.[8] In 1910, at the Trendelenburg Clinic in Leipzig, two thoracic surgeons, A. Lawen and R. Sievers, developed a volume-preset, positive pressure, electrically powered piston-cylinder ventilator with a draw-over humidifier. It was used with a tracheotomy tube during and after thoracic surgery and for a variety of disorders causing respiratory failure.[1]

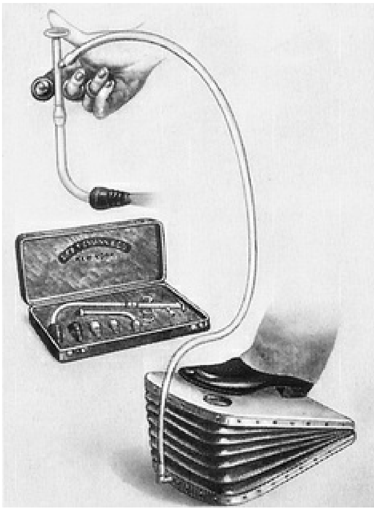

FIG. 1.1 Fell-O'Dwyer respiratory apparatus. (Reproduced with permission, Blackwell Scientific Publications, Oxford.)

Over a long career, Chevalier Jackson (1858–1955), a surgeon at Temple University in Philadelphia, developed techniques for laryngoscopy, bronchoscopy, and tracheotomy.[1] He revolutionized the procedure of tracheotomy and developed a detailed protocol of airway care. His design of tubes, made of silver, for patients of all ages set the standard for tracheotomy tubes for more than the first half of the 20th century.

In 1958 Peter Safar, then at the Baltimore City Hospital, published studies proving that the long-standing pulmonary resuscitation technique of chest-pressure arm lift was virtually worthless. In effect, he went back to Elisha and proved jaw thrust and mouth-to-mouth resuscitation superior.[11] Soon after, W.B. Kouwenhoven and James Jude at Johns Hopkins published work on the effectiveness of closed-chest cardiac massage.[12] Beck and his team, in 1946, had demonstrated open-chest electrical

defibrillation. In 1952 Zoll and coworkers proved the efficacy of external defibrillation and, in 1956, the effectiveness of external cardiac pacing.[13]

Contributions of Specific Disciplines

Pediatric Anesthesiology

PCCM developed initially through the efforts of pediatric anesthesiologists, as well as pediatric general and cardiac surgeons and neonatologists. In fact, most of the original PICUs were founded by pediatric anesthesiologists (Table 1.1).[1,4,14-24] Before discrete, geographically separate, intensive care units evolved, critically ill children often received close monitoring, intensive nursing care, and pulmonary support in the postanesthetic recovery room. There the anesthesiologists were the attending physicians with the requisite knowledge and skills for this effort. In addition to those PICUs noted in Table 1.1, there were certainly others that were not as well documented.

TABLE 1.1

Some Early Pediatric Intensive Care Units and Programs[a]

Year	Institution/Location	Medical Director(s)	Director(s) Specialty[b]
1955	Children's Hospital, Göteborg, Sweden	G. Haglund	Ped Anesth.
1961	St. Goran's Children's Hospital, Stockholm, Sweden	H. Feychting	Ped Anesth.
1961	Great Ormond Street Children's Hospital, London, England	W. Glover	Ped Anesth.
1963	Hospital St. Vincent de Paul, Paris, France	J. B. Joly G. Huault	Neonatology Neonatology
1963	Royal Children's Hospital, Melbourne, Australia	I. H. McDonald J. Stocks	Ped Anesth. Ped Anesth.
1963	Adelaide Children's Hospital, Adelaide, Australia	T. Allen I. Stevens	Ped Anesth. Ped Anesth.
1964	Alden Hey Children's Hospital Liverpool, England	G. J. Rees	Ped Anesth.
1967	Children's Hospital of Philadelphia, Philadelphia, Pennsylvania	J. J. Downes	Ped Anesth.
1967	Children's Memorial Hospital, Chicago, Illinois	D. Allen F. Seleny J. Cox	Ped Anesth. Ped Anesth. Ped Anesth.
1968[c]	Children's Hospital District of Columbia, Washington, DC[d]	C. Berlin	Ped.
1968	Children's Hospital Calvo Mackenna, Santiago de Chile	E. Bancalari	Ped.
1969	Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania	S. Kampschulte	Ped Anesth.
1969	Yale-New Haven Medical Center, New Haven, Connecticut	J. Gilman N. Talner	Ped Anesth. Ped Cardiol.
1970[e]	Hospital for Sick Children, Toronto, Canada	A. Conn	Ped Anesth.
1971	Massachusetts General Hospital, Boston, Massachusetts	D. Shannon I. D. Todres	Ped Pulm. Ped. & Ped. Anesth.
1971	Long Island Jewish Hospital, New York	B. Holtzmann	Ped Pulm.
1971	Montefiore Hospital, New York	R. Kravath	Ped Pulm.
1972	Sainte Justine Hospital, Montreal, Canada	M. Weber A. Lamarre	Ped. Ped Pulm.
1972	Children's Hospital "Dr. R. Guiterrez," Buenos Aires, Argentina	J. Sasbon	Ped.
1972	Children's Hospital "Pedro Elizade," Buenos Aires, Argentina	C. Bonno	Ped.
1972	Hospital for Sick Children, Edinburgh, Scotland	H. Simpson	Pulmonology
1974	Red Cross Children's War Memorial Hospital, Cape Town, South Africa	M. Klein	Ped Pulm.
1975	Private Hospital, Uruguay	M. Gajer	Ped.
1975	Children's National Hospital Medical Center, Washington, DC	P. R. Holbrook A. Fields	Ped. Ped.
1975	Children's Medical Center, Dallas, Texas	D. Levin F. Morriss	Ped. Ped. & Ped Anesth.
1976	Hospital Infantil La Paz, Madrid, Spain	F. Ruza	Ped.
1977	Johns Hopkins Medical Center, Baltimore, Maryland	M. C. Rogers S. Nugent	Ped. & Ped Anesth.

1977	Sheba Medical Center, Israel	F. Barzilay	Ped.
1977	Children's Hospital of San Diego, San Diego, California	B. Peterson	Ped. & Ped Anesth.
1977	Hospital de Clinicas, Sao Paulo, Brazil	A. Wong	Ped.
1978	Hospital Sãa Lucas da Puers, Porto Alegre, Brazil	P. Celiny R. Garcia	Ped.
1978	Sophia's Children's Hospital, Rotterdam, Netherlands	E. van der Voort H. van Vught	Ped. Ped.
1978	Children's Hospital of Los Angeles, Los Angeles, California	E. Arcinue	Ped.
1979	University of Minnesota Hospital, Minneapolis, Minnesota	B. Fuhrman	Ped.
1979	Hospital de Clinicas de Porto Alegre, Brazil	P. R. Carvhalho	Ped.
1980	Moffett Hospital, San Francisco, California	G. Gregory	Ped Anesth.
1980	Children's Hospital Boston, Boston, Massachusetts	R. Crone	Ped. & Ped Anesth.

[a]This is not intended to be an absolutely complete list. It is primarily comprised of units well documented in the literature and personally known to the authors.

[b]Primary specialties (not all inclusive).

[c]Although conceptual development of unit started in 1965, Dr. Berlin states the first year of operation of the present ICU was in 1969 (opened December 1968).

[d]Columbia Hospital District of Columbia was a precursor of Children's National Hospital Medical Center.

[e]This 20-bed state-of-the art unit followed an experience with four designated beds in the PACU beginning in 1964.

Adapted from references 1, 4, 14–24.

Pediatric General and Cardiac Surgery

Dr. William E. Ladd (1880–1967) at Boston Children's Hospital (BCH) pioneered the development of many techniques to operate on non-cardiac congenital malformations. His protégé, Dr. Robert Gross, first successfully operated on patent ductus arteriosus in 1937 and later on other congenital cardiac lesions.

Dr. C. Crawfoord in Sweden and Dr. Gross in Boston both successfully repaired a coarctation of the aorta in 1945. In the same year, at Johns Hopkins, Drs. Alfred Blalock (surgeon) and Helen Taussig (cardiologist) with Mr. Vivien Thomas (laboratory assistant) created the subclavian-to-pulmonary artery shunt for tetralogy of Fallot. Dr. John Gibbon at Jefferson Medical College Hospital in Philadelphia performed the first successful open-heart surgery using cardiopulmonary bypass for closure of an atrial septal defect in an adolescent girl in 1953.[1] These advances in pediatric surgery created the need for excellent and often complex postoperative care.

Dr. C. Everett Koop, who had completed surgical residency at the University of Pennsylvania in 1945, then trained in Boston with Dr. Gross for 6 months. He returned to the University of Pennsylvania and the Children's Hospital of Philadelphia (CHOP) in 1946. With the help of Dr. Leonard Bachman, director of anesthesiology, and the nursing staff, Dr. Koop developed the first neonatal surgical intensive care unit in 1962. Dr. Bachman and his young associate, John J. Downes, subsequently set up the first full PICU in North America in 1967 at CHOP.

Neonatology

Pediatric critical care owes a great debt to neonatologists and their special care nurseries.[1,4,25] The first and most prominent of these was established in the 1880s in Paris by obstetrician Etienne Tarnier and his young associate Pierre Budin at the Hospital la Charitre with a unit that had a full-time dedicated nursing staff,

incubators, gavage feeding of breast milk, and aseptic practices. These practices reduced hospital preterm infant mortality in less than a decade from 197/1000 live births to 46/1000 live births. Their work presaged the development of modern neonatal intensive care in the 20th century. In 1914 the first premature infant center in the United States was opened at Michael Reese Hospital in Chicago by Dr. Julius Hess (1876–1955). Canadian pediatrician Dr. Alfred Hart performed exchange transfusions involving peripheral artery cannulation in 1928. In 1932 Drs. Louis Diamond, Kenneth Blackfan, and James Batey at BCH determined the pathophysiology of hemolytic anemia and jaundice of erythroblastosis fetalis, and in 1948 they described exchange transfusions using a feeding tube inserted in the umbilical vein.

In the 1950s and 1960s Dr. Geoffrey Dawes at the Nuffield Institute for Medical Research at Oxford University, using fetal and newborn lambs, described for the first time the fetal and transitional circulation of mammalian newborns. In the late 1950s, Columbia University's obstetrical anesthesiologist Virginia Apgar, who had devised the Apgar score for assessing birth asphyxia, recruited Dr. L. Stanley James to develop animal and human investigation of the transitional pulmonary-cardiovascular adaptation during labor, delivery, and the postnatal period. Dr. James and his team at Columbia, and Dr. Abraham Rudolph, a South African pediatric cardiologist, and his team at Albert Einstein Medical Center in New York City and subsequently at the Cardiovascular Research Institute in San Francisco, performed extensive studies in fetal lambs, rhesus monkeys, and term and preterm human newborns that defined the human cardiopulmonary adaptation to delivery and postnatal life. They also determined the biochemical factors and time course of birth asphyxia and recovery. In 1959 a research fellow at Harvard, Dr. Mary Ellen Avery (with mentor Dr. Jere Mead), discovered deficiency of alveolar surfactant in lungs of newborns dying from respiratory distress syndrome (RDS). This discovery led to a better understanding of neonatal pulmonary disorders and eventually led to the intratracheal instillation of surfactant in newborn preterm infants to prevent or mitigate the severity of respiratory distress syndrome. In the 1960s state-of-the-art neonatal ICUs were established at Colombia-Presbyterian Hospital (Dr. Silverman), University of Pennsylvania (Dr. Boggs), Vanderbilt University (Dr. Stahlman), Toronto Hospital for Sick Children (Dr. Swyer), and the University of California at San Francisco (Dr. Tooley).

Pediatric Cardiology

As previously indicated, the vision of Dr. Taussig in devising a method to treat *blue babies* and successful cardiac operations led to infants and children who survived surgery and needed postoperative intensive care. Advances in technology, especially for imaging, have allowed clinicians to “see” into living patients with astounding accuracy. Increased understanding of anatomy and physiology has led to improved surgical and nonsurgical care for children with complex cardiopulmonary problems. Developments in cardiac catheterization and interventional radiology have enabled clinicians to treat many lesions without open-heart surgery and potentially difficult postoperative intensive care. This concept was introduced in 1968 by Dr. William Rashkind at CHOP with the introduction of the balloon atrial septostomy for infants with transposition of the great arteries. Growth of techniques that allow effective

intervention in many complex cardiac conditions, both nonsurgical and surgical, has resulted in many pediatric centers creating specific cardiac intensive care units often run by pediatric cardiac intensivists. Cognitive impairment in some infants with complex lesions or chromosomal abnormalities and the occasional development of chronic respiratory failure with dependence on mechanical ventilation for months or years are two of the occasional major sequelae of these highly successful endeavors. The value of PCCM for these cardiac patients and other critically ill children has been well documented by Dr. Jacqueline Noonan who noted, "Much success of the surgery can be attributed to a group of pediatric intensivists, pediatric intensive care units, improved ventilatory support, and trained respiratory therapists."[26]

Early Use of Mechanical Ventilation in Neonates and Children

The first series of carefully observed infants and children with respiratory failure was published in 1959. In that year, Drs. P.M. Smythe (pediatrician) and Arthur Bull (anesthesiologist) reported the first real success in mechanical ventilation of a series of neonates with respiratory failure caused by neonatal tetanus. These infants were paralyzed with curare to relax the tetanic muscle spasms and ventilated for 4 to 14 days using tracheotomy and a modified Radcliff adult ventilator.[27] Up until that time, infants or children were rarely given ventilator support for more than a few hours, with either adult ventilators or manual ventilation. Neither specifically designed pediatric ventilators nor small volume blood gas analysis was available. Dr. Smythe had to overcome these obstacles by innovation. Due to local cultural practices, Bantu children from tribal areas were particularly prone to develop tetanus. On July 13, 1957, at Groote Schuur Hospital, he performed a tracheostomy and began intermittent positive pressure ventilation for these infants with the assistance of anesthesiologist Dr. Bull. This was truly a landmark event in the evolution of PCCM. Although considered a success story in that it was the first time infants survived up to several weeks of positive pressure mechanical ventilation, the first seven of nine patients died. Eventually their survival rate reached 80% to 90%. They commented, "No praise can be too high for the nursing staff, who were all student nurses and without any special training." David Todres, a medical student at that time, was giving curare to and observing these infants, sparking his interest in critical care.

In 1963–1964 in Toronto, Drs. Paul Swyer, Maria Delivoria-Papadopoulos, and Henry Levison were the first to successfully treat a series of moribund premature infants with RDS and respiratory failure. They used positive pressure mechanical ventilation and supportive care[28] and emphasized the importance of a full-time team, including dedicated nurses and therapists as well as physicians. In 1968 Dr. George Gregory and colleagues at the University of California at San Francisco demonstrated improved survival with early use of continuous positive airway pressure (CPAP) without assisted ventilation or with positive end-expiratory pressure (PEEP) added to the mechanical ventilation regimen.[29] A prerequisite for successful long-term mechanical ventilation was the ability to maintain an endotracheal tube. An important contribution to the development of intensive care and long-term mechanical ventilation was the use of plastic endotracheal tubes for prolonged intubation and ventilation. Dr. Bernard Brandstater, an Australian trained

in Adelaide, Philadelphia, London, and San Francisco and working at the American Hospital in Beirut, Lebanon, reported prolonged nasotracheal intubation as an alternative to the tracheostomy at the First European Congress of Anesthesia in Vienna in 1962.[30]

Progress in treating a disorder leads to unforeseen complications and new disorders. Successful treatment of RDS led to some survivors with chronic lung disease (bronchopulmonary dysplasia [BPD]), retinopathy of prematurity, and hypoxic brain injury, conditions that remain significant today. Pediatric intensive care allows successful treatment of disorders previously considered hopeless, but it also results in small numbers of infants and children with long-term problems that require study, clinical commitment, and long-term advocacy for them and their families.

Poliomyelitis and Creation of the First Intensive Care Units

Poliomyelitis epidemics occurred worldwide in the early 20th century but seemed especially severe in Western Europe and North America. There was no treatment and, until the late 1920s, no effective life support for those victims with respiratory failure. Fortunately, the confluence of great scientific and clinical minds and the organizational efforts of physicians, nurses, and therapists addressing the needs of polio patients led to the creation of dedicated polio respiratory care units for patients of all ages. In 1929 Philip Drinker, an engineer, with pediatricians Louis Shaw and Charles F. McKhann at BCH published their experience with an electrically powered negative pressure, body-enclosing mechanical ventilator, later termed the *iron lung* (Fig. 1.2).[10,31]

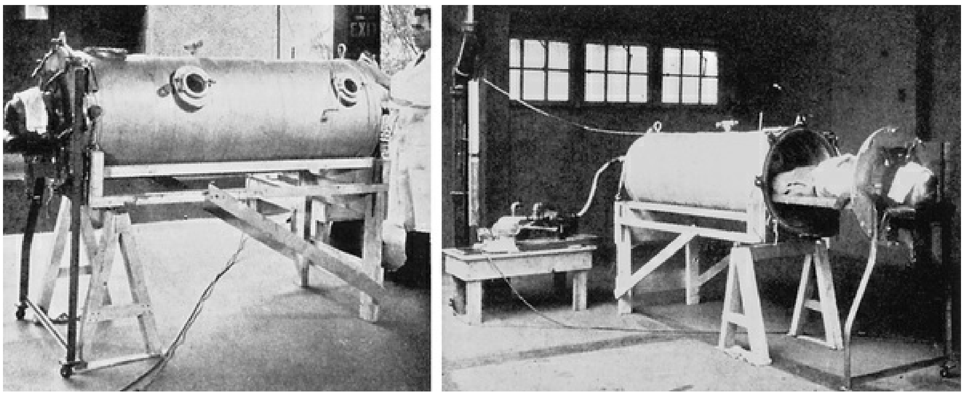

FIG. 1.2 Drinker negative pressure mechanical ventilator. (Reproduced with permission, Blackwell Scientific Publications, Oxford.)

Polio outbreaks occurred in the summer months worldwide in the 1930s and 1940s. The polio epidemics of the early 1950s were very severe in Los Angeles and Copenhagen. In 1952 Dr. H. C. Lassen, the chief epidemiologist at Blegdam Hospital in Copenhagen, described treating 2772 patients with polio. Of these, 316 were in respiratory failure and initially received assisted ventilation with iron lungs in a large respiratory care unit. During that summer, they had a census of as many as 70

patients in respiratory failure in that unit. Unfortunately the mortality of patients supported by an iron lung ventilator was nearly 90%, with the cause of death frequently being unrecognized upper airway obstruction. When the census of patients in respiratory failure exceeded the available number of iron lung ventilators, Bjorn Ibsen, the chief of anesthesiology at the hospital, with the help of his medical staff and nurse anesthetists, performed tracheal intubation and then tracheostomy along with manual positive pressure ventilation with 50% oxygen and tracheal suctioning. This care was carried out in 200 patients with respiratory failure. To provide continuous manual ventilation on a 24-hour basis, Ibsen recruited, trained, and used 200 nursing students and aides along with 200 medical students each working 8-hour shifts to provide manual ventilation, as well as 27 technicians per day to care for the patients. The mortality in patients receiving this care decreased from 90% to 40%.[32-34]

At that time, patients from outlying areas were sent in ambulances without sufficient attendants or airway care and arrived moribund. Lassen and Ibsen started to send so-called retrieval teams in ambulances out to pick up the patients in the countryside, with marked improvement in status on arrival. They also started passing stomach tubes early on for nutrition, and the rubber-cuffed tracheostomy tubes were replaced with a silver cannula that caused less tracheal mucosal damage. Even with all these improvements Dr. Ibsen noted, “Naturally we ran into a lot of complications.”[34]

Drs. Ibsen and Lassen also received help from other people who were focusing their efforts on treating polio. The clinical biochemist Dr. Poul Astrup developed a micro method to measure capillary arterialized pH and PCO_2 in infants, children, and adults. C.G. Engstrom, a Swedish anesthesiologist, designed and clinically tested the first modern volume-preset positive pressure mechanical ventilator. This spectacular and thrilling story culminated in a cohort of patients with respiratory failure being treated in a single geographic area and cared for by full-time physicians, nurses, and technicians: *the first modern intensive care unit*. Although these units tended to disband after the summer-fall polio season, they led to the creation of full-time respiratory care units at the Radcliff Infirmary of Oxford University and elsewhere in Europe and North America in the 1950s.

Soon after these events, in 1958, Peter Safar led development of the first multidisciplinary ICU in North America at Baltimore City Hospital in 1958.[35] In 1960 Barrie Fairley and colleagues created the ICU at Toronto General Hospital followed in 1962 with the ICU at Massachusetts General Hospital under Drs. Henning Pantoppidan and Henrik Bendixen.

Definitions

Some of the difficulty in telling the history of pediatric critical care medicine is defining a PICU and a pediatric intensivist. The current definitions are as follows.

Pediatric Intensive Care Unit

An ad hoc committee of the American Academy of Pediatrics, Diseases of the Chest Section established Guidelines for the Organization of Children's Intensive Care Units in July 1975.[36] In 1983 the American Academy of Pediatrics and Society of

Critical Care Medicine published Joint Guidelines for Pediatric Intensive Care Units (PICUs),[37] which were updated in 1993[38] and 2004[39] and then retired in 2013.[40] The committee defined a PICU as "a hospital unit which provides treatment to children with a wide variety of illnesses of life-threatening nature including children with highly unstable conditions and those requiring sophisticated medical and surgical treatment."

Pediatric Intensivist

Randolph and coworkers[41] defined a pediatric intensivist (in the United States) as "any one of the following: (a) a pediatrician with subspecialty training in PCCM and subspecialty certification from the American Board of Pediatrics (ABP); (b) a pediatric anesthesiologist with special competency in critical care with subspecialty certification from the American Board of Anesthesiology; (c) a pediatric surgeon with special competency in critical care with subspecialty certification from the American Board of Surgery; (d) a physician (as above) eligible for subspecialty certification by the appropriate respective board." Similar requirements for training exist or are in development elsewhere in the world.

First Pediatric Intensive Care Units

In 1955 Dr. Goran Haglund at the Children's Hospital of Göteborg, Sweden,[18] developed the first PICU, which he called a pediatric emergency ward. The patient who inspired Dr. Haglund to organize the unit was a 4-year-old boy who was operated on in 1951 for a ruptured appendix. Postoperatively, he lapsed into a coma and the surgeon declared he had done all he could and the boy would die of *bacteriotoxic coma.* The anesthesiologist offered to help and the boy was intubated, given manual positive pressure respiration with generous oxygen, tracheostomized, and given a large blood transfusion. After about 8 hours, the bowels started to function, and 4 hours later he was out of coma. After 20 hours, he had spontaneous respiration and had been successfully treated for respiratory insufficiency and shock.

This new unit had seven acute care beds with full-time nurses and nursing assistants providing 24-hour coverage. In the first 5 years, the team treated 1183 infants and children, with a mortality rate of 13.6%. Haglund went on to state, "But what we did was something else. It was the application of the basic physiology to clinical practice. Our main purpose was not to heal any disease; it was to forestall the death of the patient. The idea was—and is—to gain time, time so that the special medical or surgical therapy can have desired effects."[18] Haglund was also careful to point out that "There are few jobs more exciting, demanding, and taxing than emergency nursing. Our nurses and nurse assistants are tremendous. They must be!"[18]

Central Role of Critical Care Nursing

Although many sources emphasize the role of advanced technology in the creation of adult, neonatal, and pediatric critical care,[1,19] skilled nursing care was even more important in this evolving process. Porter[42] and others remind us of the vital role of

nursing in triage and organization of care for patients by degree of illness. Long before the organizational efforts of the 20th century, Florence Nightingale (1820–1920) organized a volunteer service with 20 nurses and created a clean environment at the British military hospital at Skutari, Turkey, in 1854 during the Crimean War. Although the care consisted mostly of hygiene and nutrition, within 6 months of her arrival the mortality rate dropped from 40% to 2%.[43] Nightingale provided the definition of nursing as "helping the patient to live."[43] These efforts were continued in the United States by Dorothea Dix (1802–1887) and Clara Barton (1821–1912), the "Angel of the Battlefield," during the American Civil War. Barton also brought the Red Cross to America in 1882.

As the complexity of medical and surgical care evolved in the late 19th and early 20th century, the need to cohort sick patients and provide skilled nursing care became apparent, especially for the premature newborn and for the victims of poliomyelitis as cited earlier. Then, as now, the recovery of the critically ill pediatric or adult patient depended on the skilled nurse at the bedside who was trained to use the life support and monitoring equipment at hand but to remain focused on the stability and comfort of the person in the bed.

In the mid-to-late 1970s, as pediatric cardiovascular surgery for more complex lesions in infants was developing, nurses provided postoperative care in designated units. Children with Reye syndrome suddenly appeared, requiring complex multisystem care. In addition, in the 1980s emergency medical services (EMS) systems began transporting severely injured children to hospitals, where they required rapid assessment and intervention by nurses and physicians and initiation of cardiorespiratory and neurologic support.[44]

Pediatric critical care nurses joined the Society of Critical Care Medicine and the American Association of Critical Care Nurses emphasizing the care of children. In the mid-1990s, pediatric critical care nurses founded their own society and established a peer-reviewed journal. Also in the 1990s, advanced practice nurses and nurse practitioners began to specialize in pediatric critical care. They continue to function as important critical care team members to augment both physician and nursing care as well as conduct clinical research.[44,45]

Role of Pediatric Anesthesiologists and Pediatricians in Founding Pediatric Critical Care Medicine

An important, early physician-directed multidisciplinary PICU in North America was established at CHOP in 1967 as an outgrowth of a hospital-wide respiratory intensive care service.[1,46] The unit consisted of an open ward of six beds equipped with bedside electronic monitoring and respiratory support capabilities and an adjacent intensive care chemistry laboratory staffed 24 hours per day. The nurses were assigned full-time to the unit, and most had previously served in the recovery room, the infant ICU, or the cardiac surgery postoperative ward. Dr. John Downes was the medical director and worked closely with two other anesthesiologists, Dr. Leonard Bachman, chief of anesthesiology, and Dr. Charles Richards, and a pediatric allergist/pulmonologist, Dr. David Wood. Four pediatric anesthesiology/critical care

fellows provided 24-hour in-unit service. Dr. C. Everett Koop (chief of surgery), Dr. William Rashkind (the father of interventional pediatric cardiology), Dr. John Waldhausen (one of the nation's few full-time pediatric cardiac surgeons and a creative thinker), Dr. Sylvan Stool (a pioneer in pediatric otolaryngology), and other staff and residents provided close, collaborative patient care, education, and clinical research.

In 1969 Dr. Peter Safar and his trainee, Stephen Kampschulte, developed a 10-bed PICU at the Children's Hospital of Pittsburgh. That same year, James Gilman, a pediatric anesthesiologist, and Norman Talner, a pediatric cardiologist, established a six-bed PICU at the Yale-New Haven Medical Center.

In 1970 at the Hospital for Sick Children in Toronto, Dr. Alan Conn resigned as director of the Department of Anesthesiology to become director of a new multidisciplinary 20-bed PICU, by the far the largest and most sophisticated unit in North America. During the prior decade Dr. Conn and his colleagues had cohorted critically ill infants and children in a sequestered area of the postanesthesia care facility where they had developed considerable expertise in critical care. This new state-of-the-art PICU was the forerunner of units developed in major pediatric centers throughout North America throughout the 1970s and beyond. Dr. Geoffrey Barker, who went on to develop one of the largest multinational fellowship training programs in the world, followed Dr. Conn.

Also in 1971 Dr. David Todres, an anesthesiologist and pediatrician, and Dr. Daniel Shannon, a pediatric pulmonologist, founded a 16-bed multidisciplinary unit for pediatric patients of all ages at the Massachusetts General Hospital.[1,4] The units in Philadelphia, Toronto, and Boston established vibrant training programs in critical care medicine and conducted clinical research. Among their numerous accomplishments, Dr. Conn became a noted authority on the management of near-drowning victims, and Dr. Todres and Dr. Downes pioneered long-term mechanical ventilation for children at home with chronic respiratory failure. These early PICUs and their training programs had a favorable impact on mortality and morbidity rates, particularly those associated with acute respiratory failure, leading to the development of similar units and programs in most major pediatric centers in North America, Western Europe, and Japan during the 1970s and early 1980s.

The development of the PICU at Children's Memorial Hospital (CMH), Northwestern University Medical School, Chicago, illustrates how many of the early PICUs evolved. The unit was first started as a four-bed area set in one of the postoperative care wards by pediatric anesthesiologists David Allen and Frank Seleny. Anesthesiologist Dr. John Cox arrived in August of 1964 and was named director. He states the unit never formally opened. It “sort of started” in the four-bed unit in the postoperative ward in 1964 and became a 14-bed separate designed unit in late 1967. Dr. Cox was the director until 1975 when he was succeeded by Dr. Richard Levin. During this time, Dr. Hisashi Nikaidoh, who was a surgery resident in 1966–1967, remembers taking care of a renal transplant patient, and the care was provided by nephrology, general surgery, and immunology without a centralized PICU service. Dr. Zehava Noah, who was educated in Israel and trained in the UK, did a critical care fellowship in anesthesia at CMH, developed a closed medical-surgical PICU in 1979, and was named the director in 1981. There was also an associate surgical director.[47-50]

Some of the early PICUs were directed by pediatricians. In 1966 Dr. Max Klein

joined Drs. H. de V. Heese and Vincent Harrison in a two-bed neonatal research unit at the Groote Shuur Hospital in Cape Town. Their research resulted in many significant papers, not the least of which was “The Significance of Grunting in Hyaline Membrane Disease,”[51] demonstrating that oxygen tensions fell when infants were not allowed to grunt. By 1969, at Red Cross War Memorial Children's Hospital in Cape Town, South Africa, pediatric patients with respiratory failure (eg, Guillain-Barré) were ventilated on the general wards, and although outcomes improved, deaths were still common. Dr. Max Klein encouraged Dr. Malcolm Bowie (consultant) to start a six-bed ICU, or “high-care ward.” After further training in South Africa and at the University of California San Francisco, in 1974, Dr. Klein returned to Cape Town where he combined the neonatal tetanus ward of Dr. Smythe and the six-bed ICU of Dr. Bowie into the first full-time PICU in South Africa.[52] It took Dr. Klein 25 years of persistent effort to create a nonsegregated PICU.

The path for pediatricians providing care for the sickest patients on a full-time basis remained unclear for an extended period. Subsequent early leaders in the field each carved out their own path. Dr. Daniel Levin completed pediatric cardiology and neonatology fellowships to learn the care of sick children. However he found few Chairs of Pediatrics interested in hiring an “intensivist.” Then, in 1975 Drs. Levin and Frances Morriss (trained in pediatrics and pediatric anesthesia) were recruited to start a PICU at Children's Medical Center of Dallas.

There were so few of this new breed of intensivists that many became directors upon completion of residency and fellowship. At the beginning, few other physicians wanted to be responsible for pediatric intensive care.[23] Eventually more pediatricians decided to devote their careers to being members of a multidisciplinary team taking care of the sickest children in hospitals on a full-time basis. In 1975 the CHOP program started to accept PCCM trainees who were pediatricians without anesthesia training.

In 1967 Dr. Peter Holbrook as a medical student at the University of Pennsylvania began a part-time job in the PICU at CHOP and developed a strong interest in PCCM. Informed at the time that one needed anesthesia training to successfully work in the PICU, Holbrook shelved the idea and entered pediatric residency training at Johns Hopkins. When the PCCM idea resurfaced he found that many still felt a physician needed anesthesia training to function in the PICU. Disagreeing with the reasoning behind such a requirement, he pursued critical care training with Dr. Peter Safar in Pittsburgh who welcomed him as a fellow in critical care medicine. In 1975 Dr. Holbrook and pediatrician Dr. Alan Fields, who also trained in Pittsburgh, were recruited to the new, modern Children's Hospital National Medical Center (Washington, DC), as pediatricians in the Department of Anesthesia to direct the PICU.

Dr. Bradley Peterson,[53] after pediatric and neonatology training and an anesthesiology residency at Stanford University, became director of the new PICU at Children's Hospital of San Diego in 1977. Dr. Bradley Fuhrman, following pediatric cardiology and neonatology fellowships, started the first PICU at University of Minnesota Hospital in 1979.[54]

Dr. George Lister,[55] after a pediatric residency at Yale and a fellowship in cardiopulmonary physiology at the University of California San Francisco (UCSF), in 1977 joined the staff at the UCSF Moffitt Hospital San Francisco, as an attending in its combined adult-pediatric ICU. Due to the director's illness, he quickly found

himself the co-director of the unit.[55] He eventually returned to Yale as an attending in the PICU and chief of the section of critical care.

Dr. Mark Rogers, after completion of pediatric residency at BCH and anesthesiology residency at Massachusetts General Hospital and pediatric cardiology fellowship at Duke, in 1975 became director of the first PICU at Johns Hopkins Hospital.[56] Subsequently, in 1980 Dr. Rogers became chair of the Department of Anesthesiology and Critical Care Medicine at Johns Hopkins and chief editor of a major textbook of pediatric intensive care (Table 1.2).

Growth of Pediatric Critical Care Medicine

The field of PCCM grew rapidly in the late 1970s and 1980s. However, there was a struggle for authority in both adult and pediatric units. The culture of intensive care

was changing from one in which each specialty service cared for its part of the patient to one in which a full-time critical care service cared for the whole patient, with help of consulting specialties.[22,89]

For PCCM to achieve its full potential, it required several elements: a national organization to provide a venue in which to meet and communicate, acceptance and validation of pediatric critical care as a subspecialty, nationally approved training requirements, and academic credibility with meaningful research.

A small group of interested physicians met at the Society of Critical Care Medicine (SCCM) National Meeting in 1979 and decided to petition the SCCM to form a section on pediatrics. The society had no subsections, but the petition was successful, and the pediatric section with Dr. Russell Raphaely as chair was formed in 1980.[1] In 1983 a committee of the SCCM developed guidelines for organization of PICUs,[37] which were regularly updated[38,39] until January 2013, after which time they were retired.[40]

In 1984, after petitions by pediatric intensivists, a Section of Critical Care Medicine was established in the American Academy of Pediatrics (AAP) with Dr. Russell Raphaely as chair.[90] These organizations then petitioned for recognition of PCCM fellowships from the American College of Graduate Medical Education (ACGME) and for the subspecialty of PCCM by the American Board of Pediatrics (ABP). Legitimization of the subspecialty was achieved with establishment of a new sub-board of Pediatric Critical Care Medicine of the ABP in 1985 and the first certifying examination in 1987, at which time 182 subspecialists were certified.[90] Certification provided a clear basis for hospital credentialing of PCCM physicians.[91] In addition to certification by the ABP, the American Board of Anesthesiology and the American Board of Surgery confer subspecialty certification with special competency in critical care. In 1989 special requirements for training in PCCM were developed by the ACGME with formally accredited programs first recognized in 1990.[92]

Growth in Numbers of Pediatric Intensive Care Units

In 1979 there were 150 PICUs of four or more beds identified, and another 42 thought to exist.[93] Most were just special care nursing units, and only 40% had a pediatric intensivist available at all times. Forty percent of the units had fewer than seven beds and only one half had affiliated transport systems. By 1995, there were 306 and in 2001 there were 349 general PICUs. Of these, 94% had a pediatric intensivist on staff. Pediatric ward beds *decreased* by 22.4% between 1980 and 1989—by 10.8% between 1990 and 1994, and by 15.7% between 1995 and 2000. During the same three time periods, PICU beds *increased* by 26.2%, 19.0%, and 12.9%, respectively.[41]

Growth in Training Programs and Education

In 1983–1984 there were 32 PCCM training programs, and the ACGME accredited 28 of them in 1990. By 2013–2014 the number had increased to 64 accredited training programs with 489 enrolled fellows, of whom about 56% are women.[94] Eighty-five percent of applicants for subspecialty board certification in 2006 intended to work exclusively as intensivists.[94]

Educational programs in PCCM have progressed considerably at the annual

SCCM, AAP, Pediatric Academic Societies (PAS), American Thoracic Society (ATS), and American College of Chest Physicians meetings, as well as at independent meetings such as the Pediatric Critical Care Colloquium (PCCC) and the World Federation of Pediatric Intensive Critical Care Societies (WFPICCS). Dr. Barker had the vision of the need to bring together pediatric intensive care from many parts of the world. This led to his founding directorship of the WFPICCS, which has done much to foster development of pediatric critical care around the world, bringing vital critical care skills and experience to benefit multiple countries. Numerous textbooks on PCCM have appeared in many languages (see Table 1.2), and the journal *Pediatric Critical Care Medicine* was launched in 2000.[95]

Academic credibility that results from meaningful scientific research has come slowly. In the early days, intensivists were mostly consumed by clinical and administrative responsibilities, but high-quality science, addressing a broad range of problems, has gradually emerged. Multiinstitutional organizations have allowed studies that require more patients than can be drawn from a single institution to be designed, funded, and completed. In the early 1990s, the Pediatric Critical Care Study Group (PCCSG) was formed.[96] It was followed by the Pediatric Acute Lung Injury and Sepsis Investigators (PALISI) network,[97-99] which employed the successful programmatic model of research developed by the Canadian Critical Care Trials Group (CCCTG).[100-102] PALISI has grown and prospered through the voluntary collaboration of more than 70 North America member PICUs.

The virtual PICU was started in 1997 to bring data management technologies to critical care. In 2004 Virtual PICU Systems (VPS) was formed by Drs. Thomas Rice and Ramesh Sachdeva (Children's Hospital and Health System of Milwaukee) and Dr. Randall Wetzell (Children's Hospital Los Angeles) in conjunction with the National Association of Children's Hospitals and Related Institutions (NACHRI) to develop a PICU registry to facilitate quality improvement and research. VPS currently has more than 125 members and a massive database describing more than 1 million critical care admissions.[103,104]

In April 2004, the *Eunice Kennedy Shriver* National Institute of Child Health and Human Development (NICHD) established funding for the first federally supported network for pediatric critical care research, the Collaborative Pediatric Critical Care Research Network (CPCCRN). The Network is a multicentered program designed to investigate the safety and efficacy of treatment and management strategies to care for critically ill children, as well as the pathophysiologic basis of critical illness and injury in childhood.[105-108]

NICHD has also supported research in PCCM by developing and supporting young investigators in the field through the Pediatric Critical Care and Trauma Scientist Development Program (PCCTSDP), a K-12 research training program. The PCCTSDP, which began in 2004 as the Pediatric Critical Care Scientist Development Program (PCCSDP), entered its third project period in 2014 under the continuing direction of Dr. Michael Dean at the University of Utah and has now expanded to include pediatric trauma physicians as well.[105]

Perhaps most notably, in 2013 NICHD created an independent branch, the Pediatric Trauma and Critical Illness Branch, to further support research in pediatric critical illness and injury. The mission of the new branch is to prevent and reduce all aspects of childhood trauma and critical illness to enhance healthy outcomes for all children across the continuum of care.[105,107,108]

The growth of education and research in PCCM has coincided with, and presumably resulted in, better care for children as reflected in the decrease in mortality from septic shock. During the period from 1958 to 1966, in patients younger than 16 years of age at the University of Minnesota, mortality in septic shock was 95%; now with PICU care it is less than 10%.[109] Drs. Murray Pollack and Timothy Yeh established the basis for studying severity-adjusted mortality in pediatrics and demonstrated that patients do better when cared for by pediatric intensivists.[110] Although many would attribute these improvements to technology and scientific advances, Dr. Yeh and others remind us that the presence of a full-time nursing and medical team and attention to basic principles rather than exotic high technology improve outcomes.[111] This is echoed by Dr. Shann's two rules of PCCM: rule 1 is "the most important thing is to get the basics exactly right all of the time"; rule 2 is "organizational issues are crucially important."[23] In addition, Yeh as well as Ibsen[34] and Orr have emphasized the important contributions of regionalization and the quality of PCCM transport teams in improving outcomes.[112,113]

Organizations, although important, are created, developed, and nurtured by people who devote a great deal of time and effort to their success. Many pediatric intensivists have contributed to these efforts and have been rightfully recognized for that. Some of the individuals from organizations in the United States are listed in Tables 1.3 through 1.6.

Cost of Success in Pediatric Critical Care Medicine

Everything comes at a cost. In the field of PCCM, as in many others, advances have led to increased financial cost, survivors with chronic disease, medical errors, and occasional dehumanization of patients. Accurate estimates of the extraordinary but often necessary financial costs of modern care of the critically ill child are difficult to obtain but are frequently high.[114,115]

Children with preexisting chronic disease and an acute critical illness have prolonged PICU stays, frequent readmissions, and the need for intensive care at home or in the rare pediatric subacute facility. Most patients with these conditions did not survive in the 1960s and early 1970s. Although we return many very sick children to complete health, a small number, often with associated complex disorders, survive but live with chronic neurologic, respiratory, cardiac, or renal disease. These children and their families usually require extraordinary medical and social support, and advocacy in order to thrive.

As PICUs have evolved, intensivists have developed greater sophistication in dealing with individual family concerns, pain management, ethical issues, palliative

care, social and spiritual needs,[116] cultural differences, and the value of involving families as members of the team by including them on daily rounds.[117] These issues are described in more detail elsewhere in this text.

Since the inception of PCCM, members of the team have experienced long hours of stressful work and occasional feelings of despair and frustration that their efforts are not making a difference. This can lead to emotional distress and a sense of loss of fulfillment in their professional lives. Understanding of this problem by local medical and nursing leaders helps the team members realize they are making an important difference through their efforts and dedication, thereby reducing burnout and enhancing staff morale.[118-120]

Around the World

People around the world have made many contributions to the evolution of PCCM, through innovative treatment of specific diseases, creating PICUs (see Table 1.1), and advancing education (see Table 1.2[121]). The following discussion highlights the global origins of PCCM but is not intended to be all inclusive.

Canada

As described earlier, Dr. Alan Conn, anesthetist-in-chief at the Hospital for Sick Children, Toronto, envisioned and successfully opened a multidisciplinary PICU for medical and surgical patients in 1971.[122] At the Children's Hospital of Montreal, a medical PICU was created in 1972 by a pediatrician, Dr. Michel Weber, and pulmonologist Dr. Andre Lamarre. Drs. Marie Gauthier, Jacques Lacroix (Universite de Montreal), and John Gordon (McGill University) in 1992 were active in the development and implementation of a fellowship program in PCCM supervised by the Royal College of Physicians and Surgeons of Canada.[123]

South Africa

As noted earlier, in 1959 Drs. P.M. Smythe and Arthur Bull conceived a brilliant therapeutic plan to treat infants afflicted with neonatal tetanus from infected umbilical cord stumps,[27] and Dr. Max Klein continued their tradition at Red Cross Children's War Memorial Hospital, opening a special unit for critically ill children in 1974 with full-time intensivists Dr. Max Klein and Drs. Louis Reynolds, Jan Vermeulen, Paul Roux, and later Andrew Argent.[4,5,124]

Japan

In the 1960s Dr. Seizo Iwai, chief of anesthesia at the National Children's Hospital in Tokyo, was the first Japanese physician to introduce mechanical ventilation and arterial blood gas analysis of critically ill infants, fostering a tradition of anesthesiologists taking care of critically ill infants and children outside of the operating room. He was a strong force in developing a close relationship with other Asian countries and invited trainees from those countries to promote teaching and pediatric critical care development in their homeland. His close working relationship with Drs. Conn and Barker in Toronto paved the way for Dr. Katsuyuki Miyasaka to

study in Toronto with Dr. Conn and in Philadelphia with Dr. Downes. Dr. Miyasaka returned to Japan in 1977 and, in October 1994, opened the first geographically distinct PICU in Japan at the National Children's Hospital and helped to found the Japanese Society of Pediatric Intensive Care. He continues to foster the development of a new generation of pediatric intensivists as a hospital director and plays a major role in facilitating this process.[125]

India

Neonatal intensive care units (NICUs) in India were established in the 1960s, first at the All India Institute of Medical Sciences, Delhi, and subsequently at teaching hospitals in other major cities.[126-128]

The first PICUs were established at major postgraduate centers (Delhi, Chennai, Chandigarh, Mumbai, and Lucknow).[129] Growth of PICUs had been mainly in the private sector, although major government teaching hospitals are also improving the PICUs in their locations. An intensive care chapter of the Indian Academy of Pediatrics (IAP) was formed in 1997, and the Pediatric Section of Intensive Care of the Indian Society of Critical Care Medicine (ISCCM) was formed in 1998.[130] Currently, 24 recognized PICUs are accredited for providing training.[131] Prompt access to the available services is critical for pediatric patients. A study at a children's hospital in Hyderabad, Andhra Pradesh, India, has shown that patients travel long distances (up to 500 km) to seek pediatric critical care, with survival inversely proportional to the distance traveled.[132] To overcome these difficulties, a bold and innovative statewide patient transport program, the Emergency Management and Research Institute (EMRI), was launched in 2005 with a fleet of 70 ambulances deployed in the state of Andhra Pradesh.[132] The public-private collaborative organization has 2500 staff including emergency medical technicians (EMTs), support staff, and associates and a call center in the capital city of Hyderabad.[133]

Australia and New Zealand

As in the United States and Canada, Australian PICUs started forming in the early 1960s, arising from wards that performed postoperative recovery care for children following congenital heart surgery,[134-141] with continuing development of PICUs in major cities. There was creative development in many centers throughout Australia, some of which are Melbourne, Adelaide, Camperdown, Brisbane, and Perth. We will present some of the history and refer the reader to a more detailed account with *AUSPIC News* edited by Frank Shann in 1993.[134]

At the Free Hospital for Sick Children Melbourne, pediatric anesthesiologists Jan H. McDonald and John Stocks developed a 10-bed multidisciplinary PICU. They conducted clinical studies, including a large study demonstrating the safety and efficacy of oral and nasal plastic endotracheal tubes for airway management of children requiring mechanical ventilation.[142]

In Adelaide Children's Hospital, Adelaide, Australia, in the early 1960s, Tom Allen and Ian Steven from the Department of Anesthesia began treating upper airway obstruction with prolonged oral and then nasal intubation.[144] Long-term mechanical ventilation using Bird ventilators commenced in 1963.[143]

Pediatric intensive care was established at Princess Margaret Hospital in Perth by

Nerida Dilworth (anesthesia) in the early 1960s. Prolonged nasal intubation was first performed in September 1963. In May 1969, a dedicated area in one of the medical wards was set aside for the care of critically ill children. The first full-time intensivists were appointed in 1986 (Alan Duncan, director, and Paul Swan, specialist). The modern 10-bed pediatric intensive care unit was opened in April 1987.[145]

Matthew Spence, an anesthesiologist, originally from Glasgow, pioneered critical care medicine for adults and children in Auckland Hospital, New Zealand, opening the first adult and pediatric ICU in 1958. Cardiac surgery for children in New Zealand started at Green Lane Hospital, Auckland, in the 1950s, and a dedicated intensive care was established there in 1963, led by the cardiac surgeon Sir Brian Barrett-Boyes and anesthesiologists Drs. Marie Simpson and Eve Scelye. The first specialized pediatric emergency transport service commenced in Victoria in 1980.[146-150]

In March 1991, Elizabeth Segedin was appointed as a full-time pediatric intensivist (with no PICU!) to plan for the development of a pediatric unit. With the building of the new hospital for children in Auckland, intensive care for children was reorganized to a single pediatric intensive care unit at the Starship, which opened on December 2, 1991, with Dr. Segedin as director.

Europe

In Europe, pediatric intensive care followed shortly after the poliomyelitis epidemic in Denmark in 1952. As described previously, in 1955 Dr. Goran Haglund, a pediatric anesthesiologist, established the first medical-surgical PICU for infants and children at the Children's Hospital in Göteborg in Sweden.[28] In 1961 Dr. Hans Feychting, also a pediatric anesthesiologist, established the first PICU at St. Goran's Children's Hospital in Stockholm, Sweden, and became recognized as a pioneer in the development of pediatric intensive care in Europe.

In France, in 1963, a newborn presented with tetanus and was admitted to l'Hôpital des Enfants Malades of Paris. Shortly afterward, Dr. Gilbert Huault and JB Joly, both neonatologists, opened the first multidisciplinary PICU in France at Saint Vincent de Paul Children's Hospital. This unit was the first pediatrician-directed PICU in Europe; it soon became a major influence on the development of PICUs. Drs. Francois Beaufils, Jean Christophe Mercier, and Denis Devictor were to play an important role in further development of European pediatric critical care medicine.[151]

In London, a pediatric anesthesiologist, William Glover, opened a unit for care of postoperative cardiac patients in 1961 at the Hospital for Sick Children in Great Ormond Street. Soon all patients needing ventilator care were admitted to that unit.[152] In 1964 a well-designed discrete 13-bed PICU was developed by Dr. G. Jackson Rees, a pediatric anesthesiologist, at the Alder Hey Children's Hospital in Liverpool. Other units soon followed, essentially serving as areas allowing prolonged postoperative support.[153]

In Spain, pediatrician Dr. Francisco Ruza started working in neonatal surgical intensive care in 1969. In 1976 he opened a multidisciplinary medical-surgical PICU for older infants and children at Hospital Infantil La Paz in Madrid. This center, directed by Dr. Ruza, has served as a major training center for pediatric intensivists

not only from Spain but from South America as well.[154] From this center, Dr. Ruza has also promoted the teaching and high-quality research related to pediatric critical pathology.

The first PICUs in the Netherlands were established in the late 1970s and early 1980s at Rotterdam's Sophia Children's Hospital under Edwin van de Voort and Hans van Vught in Rotterdam. PICUs were also developed at Wilhelmina Children's Hospital in Utrecht and Emma Children's Hospital at the Academic Medical Center in Amsterdam.[155] These PICUs are multidisciplinary, and all are part of university teaching hospitals. In 1995 the Dutch Pediatric Association established a section on Pediatric Intensive Care Medicine that certifies training of nearly all Dutch pediatric intensivists. A nationwide transport system connects this centralized care system of pediatric critical care. Units were opened in Germany[156] and Slovakia[157] as well as in Krakow, Poland, and many other European locations.

Israel

Although located in the Middle East, Israel has traditionally been part of European scientific organizations, and most pediatric intensivists in Israel trained in North America. The first PICU in Israel was established in 1977 by Dr. Zohar Barzilay as a five-bed facility located within Children's Hospital at Sheba. Israel now has 12 PICUs and two cardiac PICUs. Extracorporeal membrane oxygenation services as well as cardiac transplantation are provided nationwide as part of the national health insurance program. About 30% of the patients in many of the PICUs in Israel come from the Palestinian Authority. Palestinian physicians trained in PCCM in Israel established the first PICU in Gaza.[158,159]

Latin America

The first PICU in Latin America was established in Argentina at the Dr. Ricardo Gutierrez Children's Hospital in Buenos Aires in 1969 as part of a general surgery ward. In 1972 Dr. Jorge Sasbon became first staff director of the PICU. In 1972 a PICU was set up in Pedro de Elizalde Children's Hospital, Buenos Aries, under guidance of Dr. Clara Bonno.[23]

In Brazil in the 1970s, epidemics of polio and meningococcal disease, with a high mortality, led to the creation of small units for care of these patients. These units were precursors of PICUs later established at Hospital das Clínicas São Paolo by Dr. Anthony Wong (1977), at Hospital São Lucas in Porto Alegre by Dr. Pedro Celiny (1978), at Hospital de Clinicas de Porto Alegre (1979) by Paulo R. Carvalho, and in Rio de Janeiro. In 1982 Dr. Jefferson Piva opened a 13-bed PICU at Hospital da Criança Santo Antonio in Porto Alegre.[160]

One of the pediatric critical care pioneers in Latin America was Dr. Mauricio Gajer, a dedicated physician from Uruguay. Dr. Gajer traveled to France where he worked with Professors Huault and Beaufils. After returning to Uraguay he created the first private PICU in Montevideo, Uruguay, in 1975.

In Colombia, pediatric intensive care started in the early 1960s with postoperative care of cardiovascular patients in Clínica Shaio of Bogotá, with adult cardiologists in charge. Then in the 1970s Dr. Merizalde, a pediatrician with training in pediatric cardiology, provided care for pediatric cardiovascular patients.[161]

In 1956 at Luis Calvo Mackenna Children's Hospital, in Santiago, Chile, a single-bed postoperative care unit was started by Drs. Helmut Jager (cardiac surgeon) and Fernando Eimbecke (cardiologist). In 1968 this evolved into a five-bed PICU led by Dr. Eduardo Bancalari, a neonatologist. He was later joined by pediatricians Drs. Patricio Olivio and Jaime Cordero. In the 1980s additional PICUs developed, including one with Dr. Carlos Casar at Roberto del Rio Children's Hospital in Santiago, Chile, later directed by Dr. Bettina von Dessauer (pediatrician).[162,163] Intensivists there have devoted great effort toward developing a network and transport systems to overcome the impact of Chile's challenging geography.

Similarly, the first intensive care unit in San Jose, Costa Rica, was opened in 1969 at Hospital Nacional de Niños "Dr. Carlos Sáenz H" as a postoperative cardiac care unit. It was initially a nine-bed unit run by anesthesiologists and surgeons. Eventually pediatricians, without special PCCM training, became involved. In 1982 Dr. Aristides Baltodano trained in PCCM in Toronto, becoming the first pediatric intensivist in Costa Rica at Hospital Nacional de Niños "Dr. Carlos Sáenz H." The hospital now has a 22-bed multidisciplinary unit with more than 1000 admissions per year.[164]

Over time a critical care network throughout Latin America has improved access, transport, and specific critical care knowledge in all countries. However, there is still work to do to facilitate access to critical care and achieve results comparable to those in high-resource countries. Sociedad Latin Americana de Cuidados Intensivos Pediatricos (SLACIP) has played a crucial role. Every 2 years a Latin American Pediatric Intensive Care Congress takes place. A SLACIP symposium prior to each WFPICCS World Congress has become a tradition since the first world congress in Baltimore in 1992. The common language among more than 70 countries with many culture and challenges forms a common bond.

High-Mortality Countries

In 2013 6.3 million children died before age 5 years.[165] Over 95% of these deaths occurred in high-mortality countries, and 52% were caused by infections—especially pneumonia, diarrhea, and malaria—that could be prevented or treated at low cost.[166] Asia, for example, is the world's hot spot for the emergence and reemergence of infectious diseases that threaten the world (ie, severe acute respiratory syndrome [SARS] and influenza) but still has huge burdens of the traditional infectious diseases (malaria, tuberculosis, HIV, diarrhea, dengue, etc.). Asia also leads the world in the emerging and global export of drug resistance to many pathogens, despite undergoing a period of unprecedented economic growth. Approximately 96% of children in the world live and die in resource-poor countries. Replicating success demonstrated in many countries more broadly in India and elsewhere will have an immense impact on national resources. For example, in India, because of the high birth rates (annual births of 25 million) and large pediatric population (35% of total or approximately 300 million), as well as the need for trained people and material resources to service them, the required number of NICU and PICU beds will be enormous. It would therefore seem prudent for all district hospitals (750 in the country) to be upgraded to provide level II services that will meet the needs of rural communities.[167] Increased access to PCCM for those at all economic levels should improve survival and eventually decrease the birth rate once people are more

confident their children will live.

Although the development of PICUs is essential for the overall improvement of child survival in developing countries, the high cost of intensive care limits patients' access to PICU services.[168,169] Basic and cost-effective care have proved to have a major impact on improving the survival of infants and children. For example, a study in New Guinea demonstrated that the systematic use of pulse oximetry and supplemental oxygen reduced mortality from pneumonia by 35%.[170] However, the cost was $51 for each child, which is beyond the means for many low-income countries where a high proportion of child deaths occur.[171] Because hospital care is often not available to children in high-mortality countries, several authors have emphasized the need for preventive measures and improved primary health care.[172-177] It is therefore important to train health care personnel and families in early detection of infants and children at high risk for mortality from infections and sepsis, which lead to critical disorders such as respiratory failure. Prompt initiation of treatment can reduce the need for critical care services (Table 1.7).

TABLE 1.7

Accessibility to Pediatric Critical Care Medicine in High-Mortality Countries

Organization	Program	Purposes	References
SCCM	Pediatric Fundamental Critical Care Support (PFCCS)	1. Prioritize needs 2. Appropriate tests 3. Identify and respond to changing vital signs 4. Need for transport	178,179
BCH	OPEN Pediatrics	Free online educational platform	180,181
AAP	Helping Babies Breathe (HBB)	Neonatal resuscitation	182,183
AHA	Saving Children's Lives and Pediatric Emergency Assessment Programs (PEARS)	Resuscitation training	184
WHO	Integrated Management of Childhood Illness (IMCI)	Identify sick children early	185

Summary

The evolution of PCCM has been long and complex. It owes a great deal to innovations in anatomy, physiology, ventilation and resuscitation, anesthesia, anesthesiology, neonatology, pediatric general and cardiac surgery, pediatric cardiology, and nursing as well as to the many individuals who advanced these fields around the world. Any attempt to relate the history of PCCM is inherently incomplete. Several individuals have been recognized for their contributions to PCCM in general, and we recognize them now (Tables 1.8, 1.9, and 1.10).

CHAPTER 2

High-Reliability Pediatric Intensive Care Unit

Role of Intensivist and Team in Obtaining Optimal Outcomes

Derek S. Wheeler, Richard J. Brilli

PEARLS

- A modern pediatric intensive care unit (PICU) is a complex system, operating in conjunction with other complex systems (inpatient units, operating room, and emergency department) within and between hospitals.
- Incorporating principles of highly reliable organizations is necessary to bring about system changes that will lead to further improvements in PICU outcomes.
- As multidisciplinary PICU team leaders, pediatric intensivists should understand and manage all system aspects, not just clinical care.
- PICU structure, processes, and outcomes are key system components requiring skilled management for PICUs to achieve high reliability.
- A current and ongoing pediatric intensivist shortage is expected to influence future staffing models for physicians and nonphysician caregivers.
- Anticipated future changes in reimbursement methodology will likely influence the value proposition of current diagnostic and treatment models in an increasingly high-tech PICU world.
- Despite inherent challenges, severity-adjusted comparative data for PICU outcomes are available and useful for assessing outcomes within and between hospitals.

Introduction

An often repeated quotation states, “Every system is perfectly designed to achieve the results it gets.” This is certainly true of pediatric intensive care units (PICUs). If

PICU leaders intend to achieve better outcomes, then they must change the system. The Institute of Medicine's report, *Crossing the Quality Chasm*,[1] raised significant concerns about health care quality in the United States and called for a fundamental redesign of the US health care delivery system. Since that time, the health care industry has begun to adopt practices of other industries such as nuclear power, commercial aviation, and US Navy aircraft carrier flight deck operations that operate nearly accident free within inherently dangerous environments.[2] Organizations using these principles are referred to as high-reliability organizations (HROs), and we posit that ICUs must become HROs if outcomes are to improve further (Table 2.1).

TABLE 2.1

System Characteristics as They Relate to Differing Levels of Reliability

Low Reliability (Generally More Basic & Inconsistent) ←	Reliability →	High Reliability (Generally More Robust & Effective)
Individual preference prevails Intent to perform well Individual excellence rewarded Human vigilance for risk, error, harm Hard work, trying harder after failures Codified policies, procedures, guidelines Personal checklists Retrospective performance feedback Didactic training/retraining Awareness raising Basic standardization (equipment, brands, forms)	Personnel informed by reliability science Implementation of human factors Standardization of processes is norm Ambiguities in standard work eliminated "Work-around" solutions eliminated Reminders & decision support built in Standard checklists (real-time compliance) Good habits/behaviors leveraged Error-proofing: warnings, sensory alerts Deliberate redundancy in critical steps Key tasks scheduled/assigned Some simulation training for emergencies Real-time performance feedback	Sophisticated organizational design Integrated hierarchies, processes, teams Error-proofing: forced function, shutdown Failure modes & effects analysis Routine simulation for training/reinforcing Strong teamwork climate Strong safety culture Staff perception of psychologic safety Preoccupation with failure Reluctance to simplify interpretations Sensitivity to operations Deference to expertise Commitment to resilience

Modified from Weick KE, Sutcliffe KM. Managing the Unexpected: Resilient Performance in an Age of Uncertainty. San Francisco, CA: Jossey-Bass; 2007:194; Nolan T, Resar R, Haraden C, Griffin FA. Improving the reliability of health care, IHI Innovation Series white paper, 2004; AHRQ: Becoming a high reliability organization: operational advice for hospital leaders, AHRQ Publication No. 08-0022. Rockville, MD: Agency for Healthcare Research and Quality; 2008. http://www.ahrq.gov/qual/hroadvice/.

Studying HROs has yielded five interrelated principles that characterize how individuals in these organizations behave and think—greatly decreasing the likelihood of error and enhancing an organization's ability to quickly recover when an error occurs (Table 2.2).[2,3] "Preoccupation with failure" means treating even minor errors as potential catastrophes and learning opportunities. "Sensitivity to operations" implies that leaders pay attention to operations at all levels, especially at the front line, relying heavily on transparent, nonpunitive information dissemination to everyone. "Reluctance to simplify" recognizes dangers of oversimplification in

complex systems, and HROs actively look for differing viewpoints when analyzing events. “Deference to expertise” implies that in traditionally hierarchical organizations like hospitals, understanding of operational details for any process may reside within frontline staff. When possible, shifting operational responsibility to the front line may optimize results. Recently, greater recognition has been given to parents by including them in the frontline team.[4] “Commitment to resilience” specifies that when unforeseen events occur, HROs adapt swiftly, communicate rapidly, and solve problems creatively.

TABLE 2.2

High-Reliability Organizations: Contexts and Adaptive Characteristics

Contexts	Characteristics
Marked complexity in systems, processes, technology, and work	Preoccupation with failure
Environment is socially and/or politically unforgiving	Reluctance to simplify interpretations
Consequences for failure are potentially catastrophic	Sensitivity to operations
Cost of failure precludes learning through trial and error or traditional experimentation	Deference to expertise
	Commitment to resilience

Table copied with permission from Niedner MF, Muething SE, Sutcliffe KM. The high-reliability pediatric intensive care unit. Pediatr Clin North Am. 2013;60:563-580.

To date, high-reliability care in the US health care system remains elusive. Data from pediatric hospitals suggest recommended care is delivered only 55% of the time.[5] However, three pediatric hospital systems have reported significant harm reduction by applying HRO principles as part of robust quality improvement (QI) programs.[6-8] Further, pediatric hospitals have banded into statewide[9] and national collaboratives[10] using HRO principles and quality improvement science to lower serious safety event (SSE) rates and various hospital-acquired conditions (HACs).

PICUs are an essential, rapidly expanding part of hospital systems. Critically ill patients receive care in a PICU and, in some cases, from the PICU team “outside” the PICU. Niedner and colleagues[11] recently described the current state of US PICUs and their journey toward high reliability. They concluded that although progress has been made and many PICUs are on the journey, currently no hospital or PICU truly fulfills all of the HRO criteria. Aside from these challenges, physician leaders in the PICU must also pay attention to other aspects of the system, well beyond clinical care (eg, education of trainees, coordination of care with other disciplines), which adds challenges.[12] This chapter's purpose is to equip pediatric intensivists, as leaders of multidisciplinary PICU teams, with an enhanced understanding of the PICU as a system within the hospital system, including how to manage and evaluate PICU functioning and ultimately optimize outcomes. Integrated into this discussion are specific challenges to attaining high-reliability care delivery that exist in the current milieu. It is through implementation of this administrative knowledge, combined with clinical expertise, that a highly reliable PICU may soon develop.

PICU as System

Industrial engineering and operations research would describe hospitals and PICUs as “emergent” systems.[13] Emergence is a phenomenon in which larger systems arise from combined interactions of smaller systems in such a way that the whole is

greater than the sum of the individual components or parts. The PICU is a system with inputs and outputs. PICU inputs include critically ill patients admitted from all units within the health care system, and outputs include patients transferred back to those same units, including home. Therefore overall quality of care in the PICU cannot be viewed in isolation. Indeed, the "whole" system ("critical care") is greater than the sum of the individual components (eg, emergency department, operating room, hospital inpatient unit, interhospital transport, rehabilitation unit). Improvements at the whole system level will only occur if the PICU is viewed in its entirety, rather than as a collection of multiple, individual components. This concept has fostered a relatively new way of thinking about the modern ICU as an "ICU without walls" rather than as a distinct, geographic unit. As McQuillan stated years ago, "the greatest impact on the outcome for intensive care units may come from improvements in the input to intensive care, particularly in the quality of acute care. …"[14] The "PICU without walls" concept is perhaps best understood with the reduced morbidity and mortality that has been associated with implementation of rapid response systems and enhanced situation awareness.[15-17]

Models of Critical Care Delivery

Avedis Donabedian, an early "systems thinker" in health care, stated that health care quality should be based on three dimensions—structure, processes, and outcomes (Fig. 2.1).[18] In this model, processes are effective (1) when the right structures are in place to support them and (2) when outcomes are measured so that these processes can be evaluated for effectiveness and modified to produce better results. *Structure* refers to the setting in which care is delivered, whose elements include patients, providers, technology, and therapy.[13] Providers include the entire PICU team. When organized according to HRO principles, the team is optimally co-led by a physician and a nurse and is inclusive of all disciplines that touch the patient (Fig. 2.2). A recent trend is greater subspecialization of PICUs based on specific subpopulations of critically ill children (eg, neurointensive care, cardiac intensive care). These subspecialty PICUs are discussed elsewhere in this textbook. Structure also encompasses the physical design of the ICU, monitoring and support equipment, and information systems often equipped with decision support.[19,20] The PICU is a technical environment in which the interface between technology and humans can both improve care, as well as increase error risk. For example, computerized physician order entry (CPOE) can significantly improve quality of care provided in the ICU setting,[21] but it may also increase the risk of errors if not properly implemented or used.[22] These structural elements interact with key *processes* in the ICU to drive improved outcomes. *Processes* refer specifically to how care is provided in the ICU setting, including incorporation of high-reliability principles into daily functioning. *Outcomes* refer to end points of care, including commonly used quality and safety measures, as well as other key outcomes such as length of stay, patient/family experience, and cost/value.

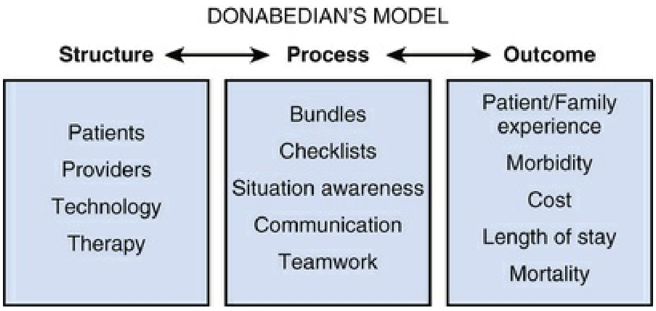

FIG. 2.1 Donabedian's model for quality. (Reproduced with permission from Donabedian A. Evaluating the quality of medical care. Milbank Mem Fund Q. 1966;44:166-206.)

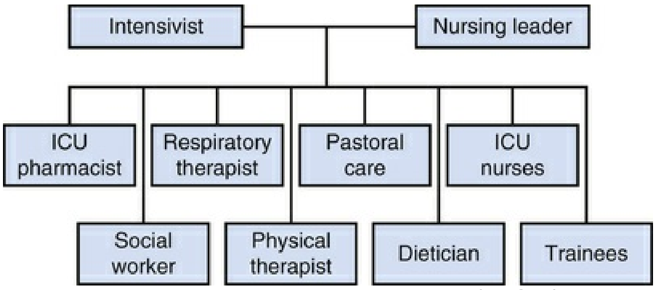

FIG. 2.2 Typical pediatric intensive care unit (PICU) team structure incorporating high-reliability organization principles. Co-leading the team with a physician and nurse together signals both "deference to expertise" and "reluctance to simplify." Inclusion of all other disciplines serving the PICU population at the same level incorporates the concept of "sensitivity to operations."

Structure

The critical care team is perhaps the most important structural component driving quality of care in the PICU. Unfortunately, there is a growing shortage of fully trained critical care providers.[23,24] These shortages are particularly relevant to various PICU physician staffing models, including high-intensity staffing and 24/7 physician coverage[25] (described later). The exact number of physicians practicing pediatric critical care medicine is unknown. A 2011 survey by the American Board of Pediatrics reported 1881 board-certified pediatric intensivists in the United States but did not account for physicians no longer practicing critical care or others (cardiologists, anesthesiologists) staffing PICUs. It also noted that pediatric intensivists are aging (average age of 49), with 25% of board-certified pediatric intensivists 56 or older.[26] Importantly, critical care physicians are retiring at an earlier age, and less than 1% of medical school graduates choose to enter critical care medicine, suggesting that these shortages will continue to worsen.[24,27] Early retirement is particularly concerning given the many studies reporting burnout as a common occurrence in critical care medicine.[28] Staffing models that incorporate more advanced practice nurses,[29,30] physician assistants,[31] and hospitalists,[32] as well as telemedicine[33] and care regionalization,[26] have been proposed as potential solutions to the critical care physician shortage.[13]

The American College of Critical Care Medicine (ACCM) Task Force on Models of

Critical Care Delivery summarized relevant literature on ICU staffing models in 2001 and again in 2015.[25] The Task Force recommended that all critically ill patients should be cared for by a multidisciplinary team of critical care providers led by an intensivist, including a critical care pharmacist.[34] In adult ICUs high-intensity staffing (previously called a “closed” model), wherein a dedicated team is directly responsible for all aspects of ICU care, is associated with better outcomes than a low-intensity staffing model (previously called an “open” model), in which patients are admitted and cared for by their primary care or subspecialty physician, often with limited input from a critical care team.[13,25,27,35]

Optimal physician coverage and direct presence in the PICU remains unclear. Several studies comparing ICUs with and without 24/7 attending critical care physician coverage have been published with a variety of results.[36] The ACCM Task Force on Models of Critical Care Delivery did not provide guidance on this issue.[25] Full 24/7 in-hospital intensivist staffing is uncommon. A 2001 study examining pediatric ICUs revealed that only 17% of all PICUs had 24/7 in-hospital intensivist physician staffing, and PICUs with more than 20 ICU beds were much more likely to provide 24/7 in-hospital intensivist staffing.[26] In a more recent study limited to pediatric and adult ICUs at academic medical centers, 33% of survey respondents indicated their hospital provided 24/7 intensivist in-house coverage.[37] Currently, evidence to support 24/7 in-hospital attending physician staffing is not compelling. A study in adults[38] suggested that a 24/7 attending coverage model was not associated with improved outcomes in ICUs with high-intensity daytime staffing. However, in those ICUs with low-intensity daytime staffing, 24/7 in-hospital intensivist presence was associated with significantly improved outcomes. Although data regarding optimal physician staffing in PICUs are limited, Arias and colleagues,[39] in a retrospective review, demonstrated a higher risk-adjusted mortality rate for critically ill children admitted to the ICU during evening hours compared with those admitted during daytime hours. Differential attending coverage between day and night was cited as a concern. Conversely, Peeters and colleagues[40] failed to demonstrate any significant differences in outcomes during off-hours admission to their PICU. Coverage at night in this PICU was provided by a resident physician, with attending physicians living close (<15 minutes) to the hospital. Others have reported similar findings.[41] Finally, Nishisaki and colleagues[42] reported that 24/7 in-hospital intensivist coverage decreased duration of mechanical ventilation and PICU length of stay but did not affect risk-adjusted mortality. For now, the issue of 24/7 in-hospital intensivist coverage and improved outcomes remains unresolved.

Optimal physician-to-patient staffing ratio in the ICU is also unclear. A study in adult ICUs[43] did not show a relationship between staffing ratios and mortality. Several studies have demonstrated an association between nursing workload and nurse retention, burnout, patient safety, and outcomes in ICUs.[28,44] We found no specific data in PICUs related to either nurse or physician staffing. The Society of Critical Care Medicine published guidelines regarding how to address this important issue but did not recommend specific physician-to-patient ratios.[45]

Process

Process refers specifically to how care is delivered in the ICU setting. The aforementioned structural elements interact with key processes to drive outcomes. It

is important to emphasize that structural elements cannot compensate for the lack of an appropriate institutional climate that supports standardized, reliable, evidence-based processes[13,25,46] and uses high-reliability principles. To illustrate, a retrospective analysis involving more than 101,000 critically ill patients receiving care at 123 ICUs in US hospitals showed that risk- and severity-adjusted mortality rates were higher for patients receiving care exclusively by critical care physicians compared with patients cared for entirely by non–critical care physicians.[47] The conclusion was *not* that intensivists were the problem but rather that there was a need for reliable processes in the ICU setting.[48] For example, intensivists may have used their personal judgment for clinical decision making instead of following a standardized protocol that may be associated with better outcomes. Given the technical and procedural-based nature of the specialty of critical care medicine, perhaps intensivists performed more invasive procedures, which could have adversely impacted outcome. Adequate structure and optimal processes, accompanied by rigorous use of high-reliability principles, are essential to drive improved outcomes. Optimal nurse and physician staffing structure will not consistently prevent an adverse drug event from causing harm if rigorous medication double-check techniques are not practiced with every medication administration.

Multiple studies have shown significant reductions in various types of patient harm in PICUs through implementing standardized, reliable processes including the use of *bundles* (Table 2.3). A *bundle* is a relatively short list of standardized, generally evidence-based or best practice interventions for a patient population or disease that, when implemented consistently, lead to improved outcomes. It is the combination of elements performed reliably and in aggregate that drive the improvement. *Checklists* have also been used to improve overall care of critically ill children admitted to the PICU. Gawande and Pronovost advocate using checklists in the ICU.[49,50] Daily goals improve communication and collaboration between team members and different disciplines of the critical care team.[51] Finally, structured communication during multidisciplinary rounds[52] and hand-offs[53,54] are additional key processes driving quality and improved outcomes in the PICU.

TABLE 2.3

Key Processes in Pediatric Intensive Care Unit (PICU)

Rounding Process	**Transitions of Care**
Daily multidisciplinary rounds (including medical and surgical subspecialists)	Medication reconciliation
Daily goals sheet	OR-to-ICU hand-offs
Daily shift huddles	Other hand-offs
Primary nursing assignments	Discharge planning
PICU leadership walk rounds	
Bundles	**Protocols**
Central line insertion bundle	Clinical pathways
VARI bundle	Standard care protocols (eg, extubation readiness testing, sedation/analgesia protocols)
Urinary catheter care bundle	Condition-specific protocols (eg, status asthmaticus, sepsis, diabetic ketoacidosis, traumatic brain injury)
Pressure ulcer prevention bundle	
Peripheral IV care bundle	

ICU, intensive care unit; IV, intravenous; OR, operating room; VARI, ventilator-associated respiratory infection.

Modified from Riley C, Poss WB, Wheeler DS. The evolving model of pediatric critical care delivery in

North America. Pediatr Clin North Am. 2013;60:545-562.

When all these elements have come together successfully, a unit has begun to function like an HRO. Several PICUs have adopted some of the characteristics of HROs to drive improvements in safety and quality.[11,55] To the degree that these principles are operational, errors and adverse events should dramatically decrease and outcomes should improve.

Outcomes

It is a challenge to compare outcomes between PICUs given the marked heterogeneity in case mix and illness severity. Although the American Academy of Pediatrics commissioned a working group to identify a list of quality measures for the pediatric ICU, it is not yet finalized. Multiple measures have been proposed,[56,57] though no single measure is likely sufficient to adequately summarize overall quality of care that a critically ill child receives in a particular PICU. It is likely that a panel of metrics, which includes both process and outcome measures, will be necessary. Similar panels, albeit without process measures, are already in use. The Preventable Harm Index is currently used to aggregate total events of harm over a given time for hospitals or groups of hospitals[9,10,58,59] and can be customized to specific units such as a PICU. Wetzel and colleagues[60] described methods to compare PICU effectiveness and efficiency. Using a data collecting network, Virtual Pediatric Systems, severity-adjusted comparisons among PICUs for LOS, efficiency, and mortality are possible.

An outcome in Donabedian's construct that deserves further mention is value. Value, at least in the current context, is a function of improving outcomes and the overall patient and family experience, while minimizing the costs of care to the patient and the health care system. We have previously emphasized that structure and process are important drivers of outcomes, which is probably true for the overall patient and family experience as well. The key in today's health care climate is to improve outcomes and family experience without incurring increased or excessive costs. Schleien has documented many financial aspects related to PICU care delivery and discusses ways to enhance revenue and decrease cost in a system, which in this country is largely fee-for-service based.[61] He anticipates that over time, it is likely that the overall payment system will shift to capitation and many incentives currently in place for overutilization of various diagnostic and therapeutic resources may shift. If this results in limitations on use of expensive unproven technologies and medications, when these services and products would have been available previously, it may present challenges for pediatric intensivists to provide high-quality care with optimal value-based outcomes.

Further impacting the cost of care is the previously described shortage in pediatric intensivists. Simple laws of supply and demand are relevant here. As the supply of adequately trained pediatric intensivists decreases, hospitals will have to pay more to recruit them. This factor, in addition to higher staffing demands on intensivists, growth of specialized ICUs (eg, CICU, NICU), and changes in duty hour requirements for trainees, will affect the professional cost of providing pediatric intensive care.

Summary

A modern PICU is a complex system interacting with multiple other complex systems. To attain, or even approach, HRO level performance, the pediatric intensivist will need more than just clinical expertise. As leader of a multidisciplinary PICU team, he or she must consistently reinforce and model HRO principles, understand and manage delivery of optimal clinical care, and deal with realities of specialist shortage, rapidly changing reimbursement mechanisms, and ever-increasing expectations of parents and patients to be team members. Intensivists have risen to great challenges in the past, and there is every reason to expect that spirit to continue.

CHAPTER 3

Subspecialization Within Pediatric Critical Care Medicine

Ann E. Thompson

PEARLS

- The tremendous expansion of scientific and medical knowledge and efforts to combine different disciplinary perspectives has led to new approaches to investigating and understanding a variety of phenomena. New fields that cross traditional boundaries between disciplines have emerged from this work.
- Interdisciplinary knowledge and research bring multiple perspectives to thought surrounding topics of interest or concern and help avoid some of the blind spots of a single discipline.
- Trends toward subsubspecialization within critical care, usually focused on patients with disorders specific to one organ system, must balance the potential for improved patient care that results from in-depth knowledge of the disorders of that system with potential loss of more general multisystem expertise.
- We seek to avoid the extremes; neither the "Jack of all trades and master of none" nor "people who know more and more about less and less, until they know everything about nothing" serves us or our patients well.
- Subsubspecialists have an obligation to develop new knowledge in their areas of critical care, identify best practices relevant to the management of disorders studied, and demonstrate improved outcomes for their patients.

Early History

Efforts to repair injury and treat diseases, often seen as possession by evil spirits or punishments by the gods, are nearly as old as humankind. Ancient artifacts include items that resemble surgical instruments, and writings from ancient Egyptian, Babylonian, and Chinese periods demonstrate efforts to understand and relieve a broad range of ailments; included are mentions of children and their illnesses.

Hippocratic physicians recognized that illnesses of younger and older children differed and were not the same as those in adults. Perhaps the first pediatric specialist was Soranus of Ephesus, who addressed infant nutrition, made recommendations about appropriate child rearing, and described symptoms of common childhood disorders. Pediatric textbooks became available in the 1400s, but even in the European[1,2] colonies of the New World where children were victims of the usual epidemics of infectious diseases as well as other illness and injury, there were essentially no physicians willing to care for them for lack of training and expertise. Care was left to family members and midwives.[3] Although there were modest advances through the 18th century, most notably the beginnings of immunization with cowpox to prevent the more deadly smallpox, rather little changed in the care of children.

Modern attention to diseases of childhood can be considered to have begun with recognition of the appalling mortality rates in childhood, largely related to infectious process, poor nutrition, and filthy living conditions, all closely related for a large majority of children. Forty percent of the deaths in Boston from 1840 to 1845 occurred in children younger than 5 years.[3] Oddly, even though neonatology would emerge as an early subspecialty of pediatrics, concern about the very high infant mortality in the late 19th century was not an immediate focus of the emerging specialty of pediatrics. Infant deaths were viewed as expected and similar to high neonatal losses in other animal species. Its emergence was an unsurprising outgrowth of pediatrics' focus on infants from its start.

In the second half of the 19th century pediatrics began to truly emerge as a distinct specialty of medicine. Advances in medical science, primarily in Europe, including among others the germ theory of disease, further understanding of biochemistry and physiology, and recognition of the cell as a basic unit of life, began to provide a footing for understanding and treating disease more as it is conducted today. In the United States, two key figures in the development of pediatrics as a specialty were Job Lewis Smith and Abraham Jacobi. Together they formed the American Pediatric Society, which was not only the first independent pediatric professional society but also the first medical specialty society in the United States. Jacobi coined the term *pediatrics* and changed fundamentally the way children were treated.

In the first quarter of the 20th century advances in medical science that defined important differences between children and adults gradually led to the recognition and acceptance of pediatrics as a distinct specialty. Attention to child welfare grew in Europe and eventually reached the United States, along with the importance of preventive aspects of medicine. A fracas between the pediatric section and the governing body of the American Medical Association (AMA) over providing health services for mothers and children led to the formation of the American Academy of Pediatrics in 1930 and the American Board of Pediatrics in 1933. The first step toward specialization in the care of children was complete.

As the 20th century progressed, effective prevention or cure of numerous infectious diseases allowed increased attention to congenital anomalies, chronic diseases, and malignancies, and technologic advances allowed new surgical procedures and extended life support, initially for neonates and subsequently for older infants and children as extensively described in Chapter 1.

The history of pediatrics and medicine in general in the 20th century was one of progressive divisions into specialty and subspecialty areas of expertise and,

increasingly, into subsubspecialization. In the United States, following the 1910 Flexner report and its emphasis on research-based education, which reflected the growing understanding of the physiologic and biochemical basis of human disease, pursuit of new knowledge increased dramatically. As physicians and scientists focused more narrowly and developed expertise around specific areas of medicine, many generalists began to devote significant portions of their practice to these more limited areas and consider themselves specialists. In 1917 ophthalmology was the first specialty area to create its own assessment board. For the remainder of the 20th century specialties proliferated; by the end of the century there were 24 specialty boards within the American Board of Medical Specialties (ABMS). Additional specialization occurred within the specialties, leading to current recognition by the ABMS of nearly 130 subspecialties.[4] In addition, it is estimated there are more than 100 self-designated specialty boards outside the ABMS.[5] As biomedical science has advanced further, there have been requests for the recognition of additional subspecialties and, increasingly, for subsubspecialties. As has occurred in other disciplines within and outside of medicine, some of these subsubspecialties have emerged from a single large subspecialty, such as cardiology (eg, interventional cardiology, cardiac electrophysiology, heart failure, and transplant cardiology), whereas others combine elements from and cross multiple disciplines such as palliative care, sports medicine, or sleep medicine (American boards of internal medicine, family medicine, pediatrics, psychiatry and neurology, otolaryngology, and anesthesiology).

Throughout recorded human history there have been evolving ways of perceiving the world and structuring ways of evaluating phenomena, discussing them, and developing solutions to perceived problems. No single perspective sees all aspects of a phenomenon or can necessarily lay claim to the correct or complete view. However, development of disciplines of thought, organized around problems and theories and ways of investigating them, have helped people conceptualize the world and communicate those concepts. One definition of discipline is "a scientific domain that uses a specific methodology, as well as a specific vocabulary … and generally constitutes the teaching domain of science" and other academic fields.[6] Over time disciplines evolve; their perceived significance changes; and they may interact in new ways, as new social or scientific needs and professions emerge.

With the tremendous expansion of scientific and medical knowledge, particularly in the last century, new approaches to investigating and understanding a variety of phenomena have resulted from combining different disciplinary perspectives. From these studies have grown new interdisciplinary theoretic and methodological identities, new fields that cross traditional boundaries between disciplines. Although there has been extensive academic discussion about somewhat confusing concepts of multidisciplinarity, interdisciplinarity, and transdisciplinarity, a definition that will suffice for the purposes of this chapter is that interdisciplinarity brings together distinctive components of knowledge, research, education, and theory of two or more disciplines. Interdisciplinary knowledge and research bring multiple perspectives to thought surrounding topics of interest or concern and help avoid some of the blind spots of a single discipline. Moreover, many complex problems require interdisciplinary approaches and yield to methods of research that combine those of multiple disciplines. Throughout modern science, and increasingly within fields of medicine, new hybrid disciplines have emerged from division and

recombination of mature specialties (Fig. 3.1A and B). As knowledge continues to increase, specialization is inevitable, because no single theory or conceptual framework can encompass all that is known, nor can any human being know all there is to know. The long-recognized field of biochemistry, providing the basis for much of our understanding of human disease, is a hybrid of biology and chemistry. Biomedical engineering, combining knowledge and research methods from biology, medicine, and engineering, is a more recent hybrid discipline. There are many more.

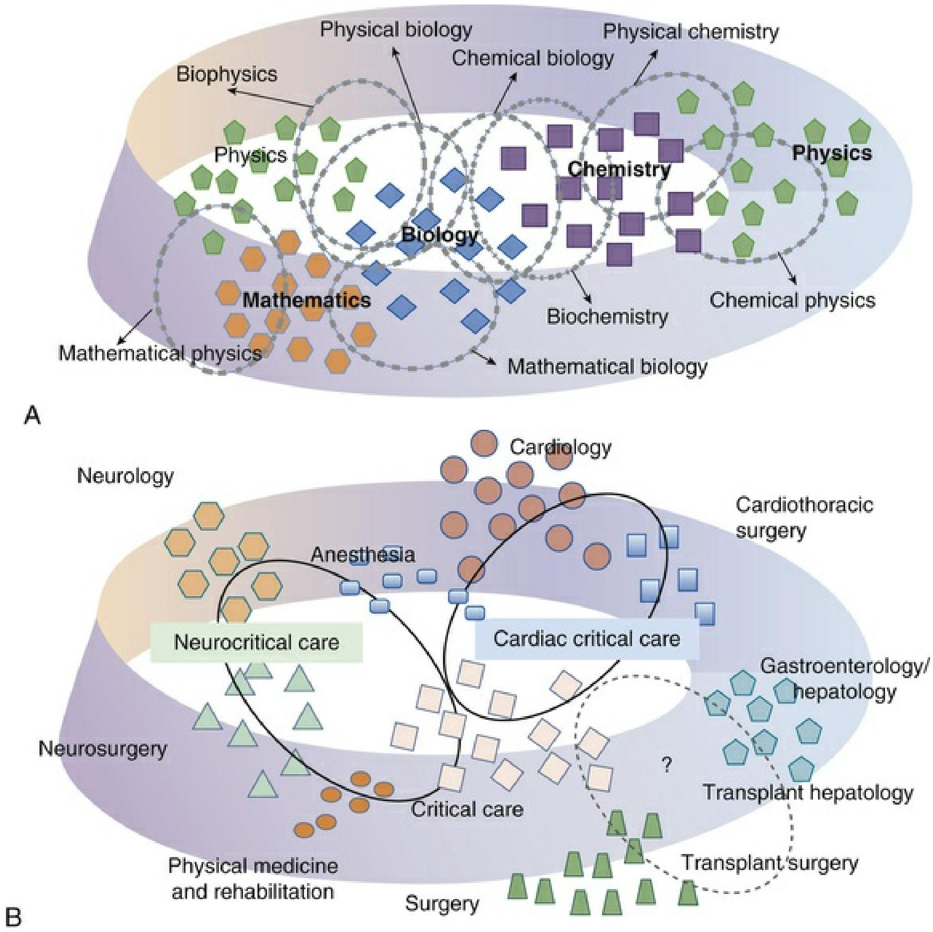

FIG. 3.1 **Emergence of New Fields of Science and Medicine. (A) Development of new disciplines from the classical mathematics, physics, chemistry, and biology. (B) Emerging subsubspecialty fields of pediatric critical care.**

Within medicine, specialization often occurs within a specialty, as was the case for cardiology, endocrinology, critical care medicine, and other subspecialties of pediatrics. However, some subspecialties cross numerous specialty lines, including sleep medicine, palliative care, sports medicine, and others, combining knowledge from dissimilar groups.

Rational progressive subspecialization requires advances in medical science and technology, professional interest, and a number of economic factors.[7] There must be a large enough patient population for subspecialists to maintain their skills. Care by a physician with additional, but potentially narrow, expertise should not result in patient care that is progressively more fragmented, with no coordination of services necessary to meet a patient's broader needs. Care by multiple specialists must at least be accompanied by excellent communication among them, significantly better

than commonly occurs at present. This is important for all patients, but it is particularly critical for the children with multiple complex problems who constitute an increasing fraction of pediatric intensive care patients.

There are significant social policy considerations as well. Does the benefit to the public of clear standards for new areas of medical knowledge outweigh the costs of training and certification that burden physicians and are likely passed on to patients? How much does increased specialization increase the cost of care? If there is increased cost, is it offset by gains in health outcomes? In addition to the highest health expenditures as a share of the gross domestic product, the United States has the largest number of specialties and subspecialties in the world—40 more than in Canada, for example—but health outcomes are not among the best.[7,8] Part of the reason for more specialties is likely the larger US population, which leads to larger numbers of patients with specific diseases and related needs, perhaps best treated by a specialist, and perhaps generating a need to relieve a generalist of a portion of the demand for care. However, the need for a sizable population to care for to maintain competence leads to a concentration of these subspecialists in large population centers and may decrease the availability of adequate expertise in small communities.[9] An additional factor that encourages specialization is that reimbursement for care provided by a specialist or subspecialist is often more generous than that provided to generalists. When that is the case, it is particularly important to be able to demonstrate improved outcomes and not simply greater expense.

Nearly every specialty board in the ABMS has grappled with the idea of specialization and its impact on the represented field as a whole and on subsequent education.[9-17] Does focus on a subset of patients lead to the specialist's loss of more general knowledge? Does the generalist lose the opportunity and skill required to care for a subset of patients? What is the impact on patient care during hours and days when one or the other is not available? Is there a need to provide duplicate physician coverage?

Arguments favoring subsubspecialization as well as board certification include the existence of a large enough and well-defined population to support specific practice, the value of setting standards and defining core competencies that define the knowledge and skill set of practitioners who label themselves specialists, reassurance to the public that the practitioner has appropriate expertise, and recognition for the work these subspecialists have done and the expertise they have developed. Opposing views include the observations that there are often multiple training pathways that lead to expertise and great difficulty merging the requirements of each (as seen in early efforts to develop unified certification in the parent field of critical care medicine); competence in managing other problems often encountered in the subspecialty population may develop through some, but not all, of these pathways; the cost of certification and its maintenance is significant; requiring subsubspecialty certification may exacerbate existing physician shortages in the field; and the data supporting improved outcome when care is provided by these practitioners are yet to be generated. These arguments were well stated in the proceedings of the 10th International Conference of the Pediatric Cardiac Intensive Care Society, but they are virtually identical to those that have been made by one specialty after another.[18]

What is the impact on education? If a resident or fellow is primarily exposed to a

series of relatively short subspecialty rotations, does he or she have an opportunity to develop competence in even the basic elements of practice? If there is little experience caring for patients not already diagnosed with a subspecialty problem, can a resident develop adequate diagnostic and problem-solving skills?

On the one hand, there is evidence from numerous walks of life that it takes many hours of practice to master a skill, whether technical or cognitive. Medicine is no exception. An intensivist becomes far more adept than does a fellow at assessing the adequacy of resuscitation from shock after caring for hundreds of patients. On the other hand, after years of practice limited to a pediatric intensive care setting, an intensivist is likely to have lost skills necessary for recognizing and treating common musculoskeletal complaints of childhood. It is likely that a similar sequence of events occurs with progressive subspecialization. The general pediatric intensivist's capacity to care for patients with congenital heart disease is likely to atrophy if he or she no longer routinely cares for such patients, whereas the cardiac intensivist is unlikely to be optimally skilled in managing a patient with meningococcemia or fulminant liver failure. In addition to the impact on each person's skill set, the human resource demands must be recognized. To maintain excellent care for all patients, coverage by both general pediatric intensivists and subspecialty intensivists must be available around the clock. These may be acceptable consequences of subspecialization if associated with improved outcome.

Intensive care has prided itself on being a multiorgan system specialty that assures that care of critically ill patients includes recognition of the impact of support for one system on others. Understanding the effect of ventilation for injured lungs on cardiovascular function; fluid management for shock on heart, lungs, and kidneys; and cardiopulmonary support on brain perfusion are core elements of skilled critical care. This expertise is believed to differ, to the benefit of critically ill patients, from the blinded approach sometimes noted in the assessment and management by physicians focused on a single organ system. Trends toward subsubspecialization within critical care, usually focused on patients with disorders specific to one organ system, must balance the potential for improved patient care that results from an in-depth knowledge of the disorders of that system with potential loss of more general multisystem expertise.

A a number of the specialty boards have addressed the question of what constitutes a subspecialty. The American Board of Internal Medicine has developed a set of criteria by which applications for subspecialty status are considered[19] (Box 3.1). In particular, a new subspecialty should include the existence of a unique body of knowledge, contribute new information and advance research, reflect a social need and improve outcomes, and outweigh any negative impact on the practice of the parent discipline or an existing subspecialty. The American Board of Pediatrics has developed similar criteria, unpublished but available from the board.[20] These criteria seek to assure that children will be better served by the establishment of the new subspecialty and that the new subspecialists will teach the content of the new discipline to learners at all levels, provide consultation to other practitioners, provide special complex care, and create new knowledge in the discipline through research (Box 3.2). These criteria would also apply to *third-tier subcertification*, or subsubspecialty certification.

Box 3.1

Criteria for Recognition as a Subspecialty

- There exists a unique body of knowledge not fully incorporated into the *parent* discipline.
- The discipline has clinical applicability to be practiced in a form distinct from the parent discipline.
- The discipline must contribute scholarly generation of new information and advance research in the field.
- There must be a social need for the discipline and evidence that its practice improves patient care.
- The discipline requires formal training with supervision and direct observation.
- Commonly the discipline involves complex technology or site-of-care opportunities for learning.
- The positive value of certification in the discipline outweighs any negative impact on the parent discipline or on basic education in its core competencies.

Adapted from the American Board of Internal Medicine. The final report of the Committee on Recognizing New and Emerging Disciplines in Internal Medicine (NEDIM)-2; http://www.abim.org/~/media/ABIM%20Public/Files/pdf/report/nedim-2-report.pdf

Box 3.2

Guidelines for Establishing a New Subspecialty in Pediatrics

- Children will be better served by the establishment of the new subspecialty.
- The subspecialist will not replace the general pediatrician in providing continuity of care.
- New subspecialists will do the following:

- Teach the discipline to medical students, residents, trainees in the subspecialty, and other health professionals
- Provide consultation in the subspecialty to general pediatricians and others
- Provide complex (usually tertiary) care and perform procedures that are special to the subspecialty

• Create new knowledge in the field through research

• The new subspecialty has a unique body of knowledge and a scientific basis.

Adult Subspecialization Within Critical Care

In the 1970s there were concerted efforts to establish a common certification examination for critical care medicine (CCM). However, representatives of the American boards of medicine, surgery, anesthesiology, and pediatrics were unable to agree on details of the required prerequisite training, and the effort collapsed.[21] Subsequently subspecialization with certification in some form developed within each specialty. Critical care in the United States is recognized by the ABMS as a subspecialty of medicine, surgery, anesthesiology, emergency medicine, and, of course, pediatrics. Certification in neurocritical care is available through the United Council for Neurological Subspecialties (UCNS) outside the ABMS and as an enfolded subspecialty 1-year program within the standard 7-year neurosurgical residency. There is interest within obstetrics and gynecology as well, and certification is available through the American Board of Anesthesiology. To date, however, none of the specialty boards have formally recognized further subsubspecialization within critical care.

The large volume of critically ill or injured adult patients meets one of the criteria for subsubspecialization. Particularly in large general hospitals, intensivists, surgeons and surgical subspecialists, internal medicine and medical subspecialists, along with nurses and hospital administrators have responded to the large population by setting up intensive care units that serve patients who suffer primarily from disorders of specific organ systems. In addition to general medical and general surgical ICUs, cardiac and cardiothoracic surgery ICUs have become common, particularly in the United States, although less so elsewhere in the world. Increasingly, units dedicated to trauma, primary pulmonary disease, neurologic disorders, and transplantation are also being established in adult facilities. In some settings intensivists spend time in several different subspecialty-focused ICUs; in others they work in a single unit.

Subspecialized Pediatric Intensive Care Units

Traditionally, pediatric intensive care units (PICUs) have been general medical-surgical units. Care models have typically included a pediatric intensivist leading a team of nurses, other ICU professionals, and often residents or fellows in collaboration with pediatric medical and surgical specialists. The degree of management control afforded the PICU team varies, but the basic structure is fairly consistent. Aside from neonatal units, ICUs developed for patients with congenital and acquired heart diseases are the only common subspecialty units, although there have been a small number of units focused on the care of burned children. Sine the early 2000s, there has been an increased focus on developing neurointensive care units.

There is evidence from adult medicine that cohorting patients with similar conditions may have a positive impact on outcome. Patients with acute myocardial

infarction benefit from care in a coronary care unit and patients with stroke are more likely to be alive, independent, and living at home 1 year later if treated in acute stroke units.[22-25] A number of retrospective studies provide evidence of improved outcome and decreased resource consumption for adult patients treated in neurocritical care units for intracerebral hemorrhage and traumatic brain injury.[26-30] The explanation for improved outcome is not entirely certain, but the presence of a neurointensivist-led team and use of evidence-based standardized protocols for management appear to be important factors.[31-33] Proponents of neurointensive care attribute improved outcome to optimal application of neuromonitoring and therapeutic advances, as well as the presence of dedicated neurointensivists,[33,34] similar to the impact of the high-intensity involvement of intensivists in general ICU outcome.[35]

In pediatrics the data are more limited. Several studies demonstrate improved outcome for children with cancer treated in specialized centers.[36-38] A study of patients admitted to a specialized unit for exacerbations of asthma may also be noteworthy.[39] These children received protocol-based care by specially trained staff, with case managers who coordinated care with the child's primary care physician and communication with families. Although not all of the outcome measures of interest (reduced length of stay, emergency department visits, and readmissions) might be directly relevant to critical care, the organization of care and communication strategies employed may be entirely applicable.

Cardiac Intensive Care

In many children's hospitals and perhaps larger pediatric services in general hospitals, infants and children with congenital or acquired heart disease constitute one of the largest PICU patient populations. In addition to the usual respiratory and cardiovascular monitoring, those with congenital heart disease, in particular, benefit from expertise regarding their hearts' structure, function, and physiology both before and after surgery, as well as skilled application of echocardiography. In the first decades of pediatric intensive care, physician care teams composed of cardiothoracic surgeons and intensivists, with intermittently involved cardiologists, provided postoperative care for these patients. Typically, surgeons maintained strong control over patient management, even when not able to be present in the PICU. The perception was that intensivists lacked sufficient cardiac expertise to provide optimal postoperative management, whereas pediatric cardiologists as a group lacked general intensive care skills and usually only rounded on patients once or twice daily or when called to evaluate specific concerns. Strong pressure from surgeons for units dedicated to the care of these patients without the distractions of other patients, along with a perception that optimal postoperative care requires special expertise that combines the skills of pediatric intensivists with those of pediatric cardiologists (as well as elements of those of neonatologists, cardiac surgeons, and cardiac anesthesiologists), resulted in what can be considered the hybrid discipline of pediatric cardiac intensive care (Fig. 3.2).

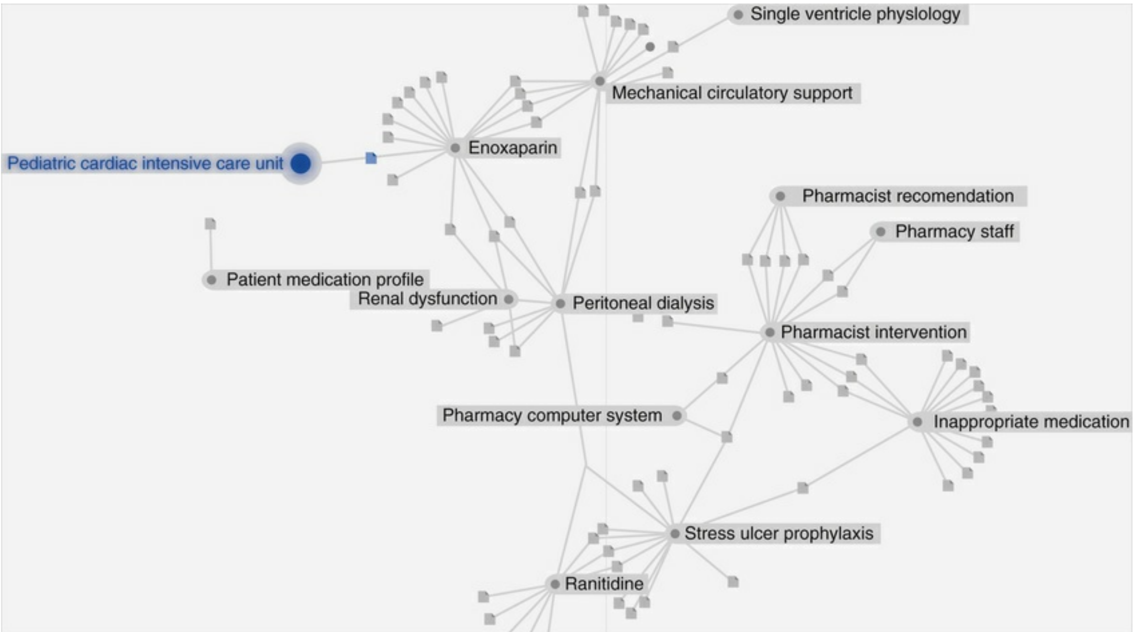

FIG. 3.2 **Multidisciplinary Strands in CICU Treatment Decisions. A single simple example of the multidisciplinary input that contributes to the practice of cardiac critical care. Many more complex examples could be generated.**

As is the case with other hybrid disciplines, there are several pathways for training. At present, these include an additional year of cardiac intensive care training for pediatric critical care–trained intensivists, an additional 9 to 12 months of intensive care training for cardiologists,[40] or combined fellowships in both pediatric cardiology and pediatric critical care medicine of 5 to 6 years.[41] Although the American Board of Pediatrics does not formally recognize this further subspecialization, at least 19 children's hospitals in the United States and Canada offer additional training to meet these guidelines, nearly all for 1 year.[42] The Society of Pediatric Cardiology Training Program Directors, the American Academy of Pediatrics, the American Heart Association, and the American College of Cardiology approved guidelines that focused on the development of specific competencies in 2015.[43] This document describes the knowledge and skills the fellow must develop, rather than defining the amount of time that needed to be spent on a subspecialty service or performing a certain number of procedures in order to complete training.

At present, many children's hospitals have distinct cardiac intensive care units, perhaps as many as half or even two-thirds of those with congenital cardiac surgery programs. Many of the remainder have dedicated cardiac beds within a general PICU.[44,45] Although staffing varies, most include specifically trained cardiac intensivists or identify a group of general intensivists who elect to spend all or most of their clinical time in the cardiac intensive care unit (CICU). Similarly, there is a growing focus on developing a nursing staff devoted to this group of patients.[44,46]

Mortality in children undergoing congenital heart surgery has improved dramatically. There is evidence that higher patient volume is associated with decreased mortality following congenital heart surgery,[47-52] and larger volume centers are more likely to have dedicated CICUs. (It should be noted that the volume-outcome relationship is strong, but not perfect; there are smaller programs that have excellent outcomes.)[53] Admission to a dedicated CICU rather than the neonatal intensive care unit has been associated with decreased resource use in

infants with prenatally diagnosed congenital heart disease.[54] To date, however, evidence does not demonstrate improved survival based on the CICU versus PICU model of postoperative care. The only studies to date examining the relationship between models of postoperative intensive care and outcome[55,56] found no relationship overall between mortality, length of stay or complications (including cardiac arrest, mechanical circulatory support, arrhythmias acute, respiratory insufficiency requiring reintubation or prolonged mechanical ventilation, renal failure requiring renal replacement therapy, new seizures or neurologic deficit, or infection), and the model of care. The Society of Thoracic Surgeons and the European Association for Cardio-Thoracic Surgery (STS-EACTS) category 3 patients, primarily including children undergoing complete atrioventricular canal repair and arterial switch for transposition of the great vessels, was the only subgroup in which a survival benefit was noted.

The volume-outcome relationship has also been demonstrated for PICUs, with larger units reporting a lower mortality.[57] Although larger centers with larger PICUs are more likely to have a separate CICU, more than a quarter of CICUs are in low-volume centers. There are currently no data that describe the volume-outcome relationship in CICUs, other than through their association with cardiac surgery programs. It is possible that outcome for these patients, whether cared for in a CICU or a PICU, is related to the organization of care in each setting. CICUs are more likely to be staffed with fellows and midlevel practitioners than with residents and attending physicians with combined cardiology and critical care expertise, but these factors have not yet been shown to impact outcome.[45] Although adequate nurse staffing has been shown to be important in many settings,[58] no clear relationship between nurse staffing and skill mix and outcome has been demonstrated for CICUs.[46] One study did identify increased risk of an unsuccessful resuscitation if the patient's primary nurse had less than a year's CICU experience. It is possible that units dedicated to the care of a specific subset of ICU patients might be characterized by greater esprit de corps, having a smaller team of physicians, nurses, and others with a special identity and dedication to a specific goal. On the other hand, many ICU nurses share critical care's multiorgan system focus, and relatively few indicate preparedness and a willingness to care for a limited population. Developing a cadre of specially trained nurses well prepared to care for these patients is a likely requirement; if accomplished it may contribute to both patient safety and esprit de corps.[59,60] In addition to well-trained staff, excellent interprofessional collaboration may be a defining characteristic of units with the best outcomes.[58,61-64]

Management of most conditions treated in ICUs varies substantially between and within institutions, and data regarding best practices are sparse. Although CICUs and other subspecialty units might be ideal settings for defining best evidence-based practices, developing treatment guidelines around them, and streamlining care, there is only limited evidence so far that this is occurring. A survey exploring hypoplastic left heart syndrome management described widely varying practices in virtually every aspect of care, regardless of the ICU model.[65] The National Pediatric Cardiology Quality Improvement Collaborative has demonstrated further variations.[66,67] Individual institutions are beginning to develop clinical process guidelines for patients undergoing and recovering from specific procedures, and these do demonstrate improved outcome, including decreased ICU and hospital length of stay and decreased resource utilization and cost.[68-72] There are ongoing

efforts to standardize practices, but comparative outcome studies have not been reported.

Of particular note to this discussion is the recognition that infants and children with congenital heart disease are at very high risk for neurodevelopmental deficits. Identifying causes of these problems, particularly those that may be responsive to treatment, is a high priority for everyone caring for these patients.[73-79] The opportunity to collaborate with other intensivists and neonatologists, especially those particularly focused on neurocritical care, represents a chance to bring together again the best skills and diverse perspectives of a variety of intensive care subspecialists.

Neurocritical Care

As outcome for nearly all critically ill infants and children has improved over the past several decades, brain injury has been left as the major cause of PICU mortality and long-term morbidity.[80] Children with neurologic disorders are more than three times more likely to die than those without, and their care is significantly more costly.[81,82] The etiology of brain injury is variable and includes patients with seizures, CNS infection, spinal cord injury, and those following neurosurgery for hydrocephalus, tumors, and epilepsy, but patients with stroke and trauma have mortality rates far in excess of those with other disorders. Patients with severe traumatic brain injury (TBI) constitute less than 1% of patients with neurologic disorders admitted to PICUs but account for nearly 30% of the mortality in this group. There are more deaths in childhood from TBI than from all childhood cancers combined or from heart disease.[80] Significantly improving mortality and morbidity in critically ill pediatric patients will require making progress with these patients.

In addition to primary neurologic disorders that prompt admission to the PICU, neurologic injury complicates the course and outcome of many other critical illnesses. Incorporating optimal care of the nervous system is an essential component in the management of shock, liver failure, sepsis, and cardiac disease, among others. Neonatologists have also begun to develop a focus on neurologic injury in their patients and have taken steps toward what might evolve as a subspecialty within their field. Infants with extreme prematurity, perinatal asphyxia, neonatal seizures, status epilepticus, and multisystem disease are all at risk for neurologic morbidity, which mars much of the dramatically improved survival in this population.[83-85] Similarly, as long-term survival has improved following repair or palliation of complex congenital heart abnormalities, it has become apparent, as noted earlier, that significant neurologic dysfunction is present in many patients.[75,76] They are at increased risk for cognitive impairment as well as impairment of gross and fine motor skills, language and communication deficits, visual perceptual deficits, and behavioral and psychologic abnormalities. Some of these deficits are related to coexisting congenital brain abnormalities, but others are acquired as secondary effects of cardiopulmonary bypass, hypoxemia, and hypoxic-ischemic events. A question arises: Should there be a subsubspecialty of critical care or neurology that focuses on all of these disorders? (See Fig. 3.3.) Or should clinician-investigators in neurocritical care identify best practices and new treatments that can be adapted to other pediatric intensive care settings?

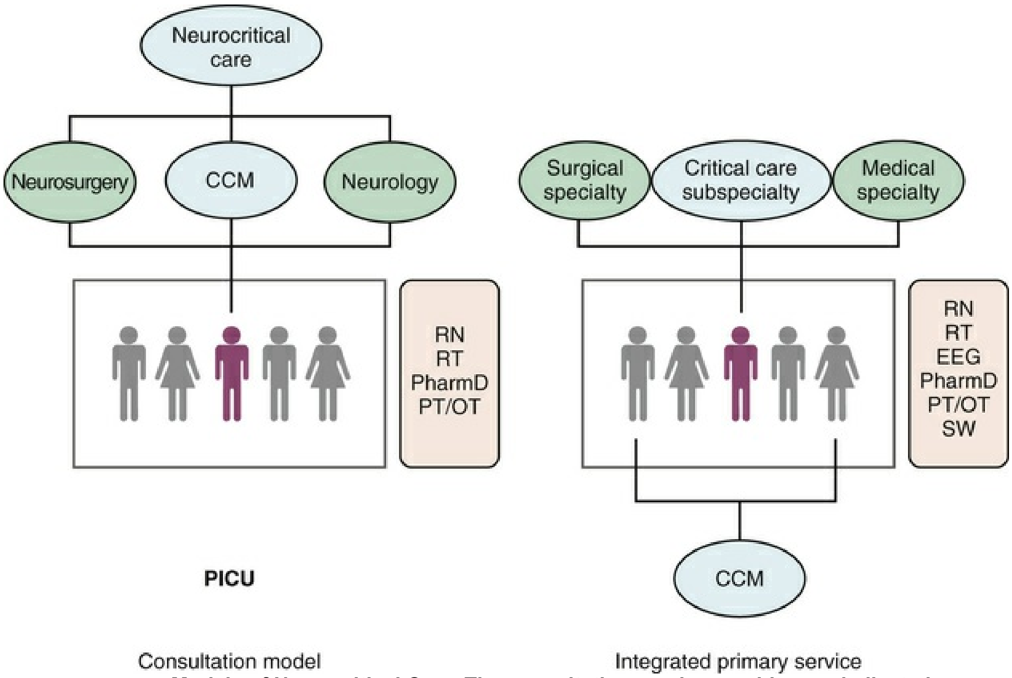

FIG. 3.3 **Models of Neurocritical Care. The consultation service combines a dedicated neurology team with the general PICU team. No new CCM resources are required, but managing variations in care is challenging. Night and weekend coverage is provided by neurology fellows on that service. The integrated neurocritical care team is led by the attending intensivist who directs a separate PICU team, with coattending physicians from neurology or neurosurgery as appropriate. Adherence to evidence-based protocols are more readily achieved. Attending level expertise is available 24/7.**

Efforts toward improving neurologic morbidity and mortality can be considered to be as old as PICUs in general, but the first defined pediatric neurocritical care service was probably the neurocritical care consultation service at Boston Children's Hospital, established in 1996.[87] In 2009 the first primary pediatric neurocritical care service was established at Children's Hospital of Pittsburgh. By 2015, there were nearly 30 pediatric neurocritical care services in the United States, mostly following a consultation model. The consultation model typically involves a core group of rotating pediatric neurologists with neurocritical care clinical and research interests who provide a consistent ICU presence. The service typically includes neurology residents who are dedicated to ICU consultation for a set period and provide round-the-clock in-house coverage. This team works with the general PICU team of attending intensivist, pulmonary and critical care medicine (PCCM) fellows, and rotating pediatric residents (Fig. 3.4A).[86] The alternative neurocritical care service model includes a pediatric neurocritical care attending (one of a defined subset of the PCCM attendings, with a subspecialty focus on neurologic illness and injury) on service daily and available at night, with a PCCM fellow and pediatric resident on service 24 hours a day (Fig. 3.4B). A neurologist or neurosurgeon serves as a coattending representative for relevant patients. Regardless of the model, the goal is to “resuscitate and support the acutely ill neurologic patient, minimize secondary neurologic injury and medical complications, and expedite and facilitate the patient's transition to a recovery environment.”[87,88]

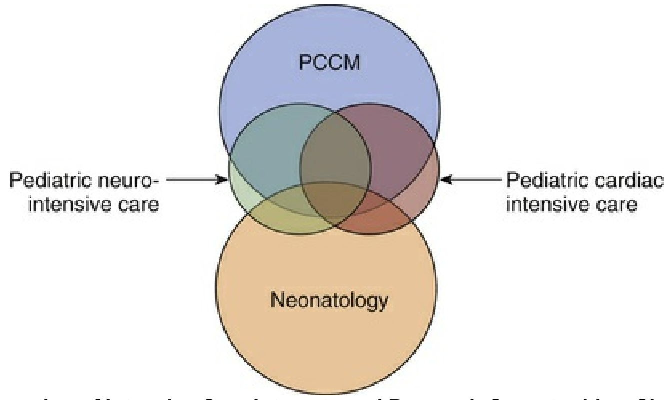

FIG. 3.4 Intersection of Intensive Care Interests and Research Opportunities. Shared concerns related to, in particular, residual neurologic morbidity provide an opportunity to collaborate with other intensivists and neonatologists and a chance to bring together again the best skills and diverse perspectives of a variety of intensive care subspecialists.

Several children's hospitals now offer additional fellowship training in pediatric neurocritical care, often with a track for physicians previously trained in critical care and another for physicians trained in neurology. In the absence of specialty board requirements, programs vary, but curricula include regular focused lectures and conferences, experience in neurophysiologic imaging and monitoring, experience diagnosing and managing neurosurgical disorders, exposure to interventional radiology and adult neurocritical care, follow-up outpatient care, physical medicine and rehabilitation exposure, and research related to the management of this patient population. Some include an element of cardiac intensive care and neonatology with a focused interest in neurologic monitoring and neuroprotection.

As is the case with cardiac critical care, evidence for improved outcome following establishment of a pediatric neurocritical care unit is sparse. Efforts are being made to identify risk factors related to outcome in these patients.[89,90] However, a retrospective review of outcome following severe TBI before and after a neurocritical care service demonstrated risk-adjusted increased discharge home without assistance and decreased mortality.[91]

Adequate “Dose” of Subsubspecialty Training

An additional question that needs to be addressed is that of the appropriate “dose” of education around the management of patients with cardiac or neurologic dysfunction or any other subset of PICU patients if they are treated separately from the general population. The Residency Review Committee (RRC) for Pediatrics of the American Council on Graduate Medical Education (ACGME) has set requirements for PCCM fellowships. There must be “an affiliated cardiac surgical program with a volume of at least 100 cases per year,” and, if there is a separate CICU, “provision must be made for fellows to have substantial patient care experience in the pediatric cardiac surgical ICU, and such rotations should be considered mandatory rather than elective experiences.”[92]

No such requirements have been set for any other subset of patients to date. The RRC has limited the time that can be spent in a CICU to 6 months of the 3-year PCCM fellowship. Although other intensive care experiences (examples provided include patients from outside the usual PICU population such as adult medical and neonatology) may be part of the program, these must be limited to 4 months overall

and must not replace time in the PICU.[93] These requirements predate the emergence of neurocritical care or any other potential subsubspecialty population.

Although the minimum number of patients (at least for cardiac surgery) and the maximum time devoted to them in settings outside the PICU are included in program requirements, these requirements are based on expert opinion. There are currently no data that define the number of patients or location of their care that results in optimal or even adequate education. It is not known whether "bolus" doses of focused subsubspecialty care rather than a steady infusion of caring for similar patients over 3 years results in a better retention of knowledge and skills. Even if both have the potential to be similarly effective in achieving a steady state, the half-life of knowledge that results from intermittent exposure is unknown. Is 1 month each year sufficient, or is the fellow starting over each time? Are the benefits of a steady infusion over 3 years of similar patient experiences in a general PICU lost in the distractions created by a need to attend to many types of patients all the time?

In addition to the impact of subspecialty ICUs on acquisition of knowledge related to a group of patients with specific organ-system disease, the impact on other educational opportunities appears to be significant. Fellowship programs with separate CICUs report more total required ICU months (16 versus 13 months) than those without. The impact appears to be greatest on elective experiences such as adult or neonatal ICU time, pain management service, toxicology/poison control center exposure, or interventional radiology, among others.[94]

Impact on Research

Pediatric critical care medicine is a young subspecialty, and research addressing topics of major interest is even younger. However, since the late 1990s, there has been substantive progress in training investigators and conducting both basic and clinical studies (see also Chapter 7). In every area of medicine most new knowledge has been generated by physicians and scientists who devote themselves to a field full time. In addition to the impact of focused clinical practice that subspecialization may bring, there is an opportunity to advance our understanding of the biology underlying specific disease processes and develop new management strategies. There is early evidence that this is occurring.

The Pediatric Heart Network (PHN), supported by the National Heart, Lung, and Blood Institute, was formed following recognition that although the incidence of congenital heart disease is at least triple that of childhood cancer, there has been little related research. The network is intended to allow multi-institutional studies to overcome the small number of patients with specific diagnoses at any given studies. The PHN also supports nursing, health services, and quality improvement research, as well as a program of clinical research mentoring. Relatively few of the studies to date have addressed CICU aspects of care, but others are ongoing.[95]

The Pediatric Neurocritical Care Research Group[96] is a group of investigators from multiple disciplines, including pediatric critical care, pediatric neurology, pediatric neurosurgery, pediatric anesthesia, and pediatric rehabilitation medicine, from more than 30 institutions in four countries. The group is dedicated to performing studies focused on optimizing functional outcomes for critically ill children with neurologic conditions. Current investigations address multiple aspects of traumatic brain injury, nonconvulsive status epilepticus in children, and biomarkers of brain injury in

extracorporeal membrane oxygenation patients, among others.

At present it is not possible to draw an adequately informed conclusion about the value of further subspecialization within pediatric critical care medicine or even to affirm the value of existing “almost” subsubspecialties. Data related to their current impact or their likely future impact on patient outcomes or educational results remain limited. From a health policy perspective, whether the trend toward further subspecialization advances the goals of improving medical care, impacting population health, and managing cost remains to be determined.[9] It does appear that the existing subsubspecialty groups are facilitating research by bringing problems of particular importance for certain patient groups into clearer focus and drawing interested investigators into more coherent groups (eg, Pediatric Heart Network (PHN), the Pediatric Neurocritical Care Research Group) that are able to address them. It may be that identification of best practices and results of this research disseminated to the pediatric critical care medicine community as a whole will be the most important outcome of limited additional subspecialization.

CHAPTER 4

Critical Communication in the Pediatric Intensive Care Unit

Shelina M. Jamal, Katherine Banker, Harris P. Baden

PEARLS

- Recognition of a high rate of medical errors resulting from ineffective communication and teamwork compelled development of strategies and tools to promote situational awareness and a shared mental model in the health care setting.
- Using specific design elements in the intensive care unit (ICU) can enhance patient surveillance and nonverbal communication.
- Applying standardized work such as organized huddles, checklists, and structured rounds can result in less variability and more consistent communication within multidisciplinary ICU care teams.
- Intentional and ongoing education and assessment of communication skills, such as closed-loop communication, and using techniques such as simulation and debriefing are vital.
- Implementation of interdisciplinary team training provides skills that improve teamwork, enhance communication, and contribute to patient safety.

"Safety first" is the mantra of 21st century American health care since the Institute of Medicine's 1999 publication, "To Err Is Human: Building a Safer Health System."[1] That groundbreaking report drew attention to the high rate of medical errors resulting from ineffective communication and teamwork and compelled an industry-wide effort to transform health care delivery systems and practices. Contemporary pediatric intensive care units (ICUs) are highly technical and data-rich environments, with specialized, multidisciplinary care teams that are ever rotating to provide 24/7 coverage. Accordingly, establishment of an effective and reliable system of communication is imperative in every ICU.

Various schemes and tools are available to optimize communication and mitigate

risk. Common to all is the focus on ensuring that every member of the health care team, including the patient, is “on the same page.” For example, borrowing from the US Department of Defense and other high-reliability industries, the Agency for Healthcare Research and Quality developed TeamSTEPPS, a collection of strategies and tools to promote “situational awareness” and development of a “shared mental model” by fostering communication, leadership, situation monitoring, and mutual support, all rooted in team structure and dynamics.[2] Dr. Mica Endsley, Chief Scientist of the US Air Force, pioneered the development and evaluation of systems to support human situation awareness and decision making, which she defined as “the perception of elements in the environment within a volume of time and space, the comprehension of their meaning, and the projection of their status in the near future.”[3] Kenneth Craik, philosopher and psychologist, first described the concept of mental models as an explanation of an individual's thought process about a particular situation that can be influenced by the surrounding circumstances, team member dynamics, and a person's intuitive perception.[4] Mental models shape behavior and set an approach, a personal algorithm, to solving problems. In the team setting, it is imperative that all individual members share the same mental model.

This chapter describes communication tools and other techniques to enhance situational awareness and the development of a shared mental model as ways of improving patient safety in the critical care setting. Comprehensive efforts encompass ICU design, monitoring systems, electronic medical records, patient flow schemes, closed-loop communication, staffing models, and team training. The authors discuss verbal and visual communication strategies that have been deployed in the medical setting with successful and sustainable results.

Intensive Care Unit Design

According to the 2012 Society of Critical Care Medicine's Guidelines, optimal ICU design can help reduce medical errors, improve patient outcomes, reduce length of stay, increase social support for patients, and play a role in reducing patient cost.[5] Private rooms enhance the patient and family experience, and minimizing noise and disturbances can promote the healing process.[6-8] On the other hand, published reports describe a correlation between lower ICU visibility and increased mortality.[9] As a consequence, reliable monitoring systems are crucial to patient safety and quality of care. This includes not only bedside monitoring but also remote monitoring of patients from central workstations and throughout the ICU. Several design elements can enhance situational awareness, patient surveillance, and nonverbal communication in the ICU.

In patient rooms:

- Monitoring should be visible from the door and the care team's workspace.
- Display boards in the room can be used for daily care plans, patient and family questions, and family contact information.
- Signage in the room can convey information to care team members, ancillary staff, and families (eg, isolation requirements, fracture risk, fall risk, difficult airway, or an open chest).
- Boards outside the patient's room identify the nurse, responsible physician, and contact information.

Within the ICU:

- Remote centralized monitoring should be in place so that even when not in the vicinity of the patient, their monitoring is visible (eg, monitors at various places in the unit itself, conference rooms, call rooms).
- A central board near the main workstation shows the physical layout of the unit, patient location, nursing assignment, admits and transfers for the day, the care team, and their contact information.
- Signage denoting a sterile procedure is in progress creates a physical barrier to encourage nonessential personnel to avoid the area, as well as promoting situational awareness within the greater ICU team.
- Remote access to operating room boards or intraoperative cameras allows the ICU team to follow a patient's progress and be prepared for the patient arrival.

Medical Record

Extracting useful information from the electronic medical record can be challenging. Alerts and notifications regarding code status, medication allergies, or important social issues allow rapid orientation to the patient's status and care plan. In development are monitoring and prediction models that take patient data (ie, from the telemetry monitors) and identify patterns that might warn of impending clinical deterioration. Likewise, these techniques may be helpful in retrospective reviews for quality improvement purposes.

Huddles

Huddles are brief gatherings that bring team members together to create a shared mental model regarding a distinct procedure or event, or a status update across the entire ICU.[10-12] They should include team introductions, review of planned activities, anticipation of problems that may arise, and creation of contingency plans. Huddles serve to activate teams, empowering each team member to share responsibility in the completion of the task, while encouraging openness and trust among the team, facilitating communication, and improving overall situational awareness.[10]

Keys to successful implementation of huddles in a medical setting include these criteria[13-15]:

- Designation of a leader
- Mandatory participation of *all* team members
- Incorporation into standard work practice
- Time limits of 10 minutes or less
- Occurrence in a central location

Huddles can be used in these and other scenarios:

- Admission, to facilitate communication to review events, create a care plan, and highlight risks/concerns
- Periprocedure to orient the team, define roles, and identify potential pitfalls and contingency plans

- ICU day/night shift changes to review expected procedures, admissions, transfers, discharges, and high-acuity patients

- ICU workflow management to discuss planned ICU admissions and discharges, as well as their impact on staffing, bed availability, and hospital census

- Daily check-in (a health care performance initiative),[16] for a focused and directed conversation to address safety/quality issues from the past 24 hours, anticipated safety/quality issues in the next 24 hours, and status reports on issues identified that day or day prior

Checklists

Checklists have been widely adopted by the health care industry, with demonstrated reductions in morbidity, mortality, and preventable errors.[17-20] A commonly used checklist is the Universal Protocol, created in 2004 by The Joint Commission Board of Commissioners, to address the wrong-site, wrong-procedure, and wrong-person surgery and other procedures.[21-22] A 2010 survey found more than 90% of respondents agreed or strongly agreed that there was benefit in using the Universal Protocol in hospital units where invasive procedures are performed.

Well-constructed checklists serve as follows:

- Function as communication tools with demonstrated benefit in routine procedures (eg, extubation, procedural sedation, MRI screening, and preoperative screening) and less frequent occurrences (eg, extracorporeal membrane oxygenation [ECMO] cannulation, computer downtime).[23-28]
- Increase the reliability of care processes. Checklists performed at the end of rounds have been shown to reduce central line–associated bloodstream infections, optimize nutrition, enhance sedation weaning, etc.[29-32]
- Serve as evaluation/audit tools.

Though creation and implementation of checklists are important, shifting the culture and behaviors of those using the checklist is what determines success. Implementing mandatory checklists with limited focus on transformation of attitudes can result in no change in outcomes.[33]

Rounds

Performance of daily rounds in a standardized format results in less variability and more consistent communication within the team. To ensure a shared mental model and optimize situational awareness, all team members (eg, physicians, nurses, pharmacists, nutritionists, family members) should participate on rounds in preassigned roles. Structured reporting of data and presentation of information ensures that no issues are missed and all concerns are addressed. Daily rounds

conclude with review of safety checks and order read-back: closed-loop communication with all team members that re-enforces the shared mental model.

Closed-Looped Communication

Deficiencies in verbal communication impair the development of team structure, collaboration, and task performance.[34-35] Standardized methods of communication have been developed to promote safety and efficiency, thereby reducing the risk of team breakdowns.[36-37] A common method used in health care settings is closed-loop communication, which involves three steps:

1. Sender transmits a message using standardized terminology

2. Receiver accepts the message and verbally acknowledges receipt and understanding

3. Sender verifies that the message has been received and interpreted correctly

Transitions of Care

Reliable communication is essential at times of transitions of care. Duty-hour restrictions for physicians in training have led to increased hand-offs and the potential for discontinuity in patient care.[38] Consistent use of a hand-off tool (eg, *I-PASS*: *I*llness Severity, *P*atient Summary, *A*ction List, *S*ituation Awareness and Contingency Plans, *S*ynthesis by Receiver) has been associated with reductions in medical errors and preventable adverse events, as well as improvements in communication, without a negative effect on workflow.[39] Transfers between hospitals to the ICU can be especially high risk as they involve transport of critically ill patients, variable team members and skillsets, and resources limited by space and mobility. Transmission of clear, concise, and accurate information is imperative (see also Chapter 18).

Creation of a "Communication Center" can facilitate this process by doing the following:

- Using a single phone number for all referring hospitals and providers wishing to initiate transfer of a patient
- Recording phone conversations to clarify information transmitted, as well as quality improvement initiatives
- Conferencing simultaneously with multiple team members
- Ensuring prompt and reliable access to the transport team while en route

Medical Training

The *Accreditation Council for Graduate Medical Education* requires that Pediatric Critical Care Medicine fellows "demonstrate interpersonal and communication skills that result in the effective exchange of information and collaboration with patients, their families, and health professionals."[40] Communication is also a cornerstone of effective team leadership and is a key feature of Pediatric Advanced Life Support

training.[41] Staff perceptions of teamwork and team behavior are related to the quality and safety of patient care and identify aspects of communication and teamwork that lead to safer patient care.[42] Additionally, evaluation of a trainee's ability to communicate is changing with the development of clinical competencies and milestones (see also Chapter 22). Intentional education and assessment of communication skills are a growing expectation.[43]

Incorporating communication into medical training comprises these and many other ways:

- A longitudinal curriculum during undergraduate or graduate medical training
- Strategies specific to a certain rotation or environment
- Focus on communication as a marker for ongoing quality improvement

One effective means of teaching and evaluating communication in the ICU is through the use of simulation.[44] Simulation scenarios focused on closed-loop communication skills, such as clarity of roles and responsibilities, order repeat-backs, clarifying questions, knowledge sharing, reevaluation and summarizing, and mutual respect, give ICU staff the opportunity to practice in a high-fidelity, low-risk environment.[45-49] Some scenarios, like an ECMO cannulation, allow for incorporation of multiple disciplines (eg, physicians, trainees, nurses, respiratory therapists) leading to more realistic simulation of infrequent, high-risk events that require precise teamwork.[50-51] Simulation is further enhanced with thorough debriefing.

Debriefing

"Debriefing" originated in the military (analyzing a mission after it is completed) and gained traction in critical incident reviews (mitigating stress following critical events).[52] According to Kolb, the process of reflective observation is a cornerstone of lifelong adult learning.[53] In medical simulation, debriefing is facilitated reflection that leads participants to analyze and learn from an event.[52] Debriefing is also helpful after high-risk, infrequent events and after any event team members find particularly challenging. Effective debriefing can improve skill acquisition and retention, as well as staff satisfaction.[41,54-57]

In general, debriefing includes the following[58-65]:

- Structure: Phases include description, analogy/analysis, and application. A communication tool ensures that key points are addressed and the process is standardized.
- Content: Focus can include communication, medical management processes, and logistics.
- Participation: Team members should be active participants in self-reflection.
- Action items: Development of reliable method for follow-up is essential.

Team Training

The Institute of Medicine calls for interdisciplinary team training programs for critical care settings.[1] Extensive team training curricula based on concepts central to Crew Resource Management (CRM) exist and continue to evolve.[66-71] Examples include TeamSTEPPS and Veterans Affairs Medical Team Training (VA MTT).

Common themes among these programs emerge[67]:

- Developing communication strategies that flatten hierarchy and encourage team member assertiveness
- Cross-training to tasks, duties, and responsibilities of all team roles
- Simulating errors and contingencies
- Conducting facilitated debriefings
- Creating shared mental models and situational awareness
- Encouraging closed-loop communication

Deliberate and ongoing team training and evaluation are imperative to sustaining improvement in patient safety.[72-75]

Conclusion

Intensive care units are high-stake, high-risk environments. Reliable and accurate communication are essential to optimizing patient care and safety. An ICU focused on safety is characterized by thoughtful design, reliable organizational systems of communication, and unwavering commitment to teamwork. These elements foster a shared mental model and improve situational awareness among all team members, leading to greater efficiency and safer health care delivery.

CHAPTER 5

Professionalism in Pediatric Critical Care

Bradley P. Fuhrman

PEARLS

- The medical profession is largely self-regulated and confers many benefits on its members.
- To sustain these professional benefits, physicians must honor their contract with society.
- Professionalism is, in its simplest form, putting the patient first, placing altruism before self-interest.
- Beyond that, professionalism is a more complete charter that ties altruism to the concrete realities of the doctor-patient relationship and the marketplace in which doctors practice.
- The Physician Charter is grounded in the principles of altruism, patient autonomy, and social justice. It represents the physician's contract with society.

Pediatric critical care medicine (PCCM) is a profession. To be certified and practice as a pediatric intensivist, individuals must master several bodies of special knowledge, complete apprenticeships in pediatrics and pediatric critical care, earn various educational certificates, pass examinations (the culmination of which is the American Board of Pediatrics certifying examination in pediatric critical care), and be granted a license by a state medical board. PCCM as a profession oversees that process much as a guild controls its members and membership. As a profession, pediatric intensivists train themselves, test themselves, credential themselves, and discipline themselves. Pediatric intensivists derive many benefits from their status as professionals. They are paid as professionals, respected as professionals, and valued by society as professionals.

There exist contracts between professions and society. In exchange for the benefits "professionalism" confers and the autonomy, self-governance, and control of licensure that physicians are granted, society expects physicians to meet its needs within the boundaries of their expertise. Physicians gain the advantages listed earlier because they provide the quality of service that society requires.

Professionalism is, in the end, the set of responsibilities and behaviors that fulfill physicians' contract with society. These characteristics exemplify the good and virtuous doctor because that is the model society would hold physicians to, not because virtue has intrinsic value (which it does), but because deviation from virtue breaks the contract.

The Virtuous Doctor

Most would agree as to which characteristics exemplify the good and virtuous doctor. Society has watched doctors portrayed on television for decades in the persons of James Kildare, Konrad Styner, David Zorba, Ben Casey, Meredith Grey, and Marcus Welby. These are the characters that physicians' parents, as well as the rest of society, expect physicians to emulate. But over the past 15 to 20 years the professional organizations of medicine have obsessed over defining, teaching, assessing, and understanding professionalism. The reader might ask, "why is that?"

The Stakes

Health care now consumes (produces) about 17% of the US gross domestic product.[1] It has become increasingly technology intense and engages financial giants in the form of pharmaceutical companies, device/equipment manufacturers, and information storage/management enterprises. It employs about 14,000,000 workers.[2] Two of the largest third-party payers are Medicare and Medicaid, which together expend 4.7% of the gross domestic product on health care. Those payments flow from the general (tax) coffers to individual physicians among other recipients. We now live in a "medical marketplace"[3] and hear patients referred to by administrators as "customers" or by insurers as "covered lives." How physicians manage patients in this context is of great financial import, so it should be no surprise that many of the traits characterized as professionalism have financial implications.

The Great Paradox of the Medical Profession

A constant tension pervades medicine where principles of "self-interest" and "altruism" coexist.[4] In most human endeavors, it is considered appropriate to identify individuals' best interests and make decisions accordingly. It is in one's best interest to obey the law, brush one's teeth, and work for a living. Yet it is in the best interest of society for physicians to treat patients altruistically. The physician's pledge to society is to be altruistic in dealing with patients, to put the patient first, before oneself. These two principles, self-interest and altruism, are polarized and often conflict. With each medical decision come these questions: "Was this for the patient or for the doctor? Whose interest did this serve?" In its simplest sense, professionalism in medicine comes down to putting the patient first.

The reader may consider a concrete example: It is 4 am. A pediatric intensivist hasn't slept a wink and is hard at work in the pediatric intensive care unit (PICU) trying to finish his documentation so that he can catch some shuteye. The emergency department (ED) resident calls. He has a child with a fever who looks sick. He asks if the intensivist would mind taking a look to see if the child needs to come to the

PICU. What should the pediatric intensivist do?

1. Go take a look at the child.

2. Have the child admitted to general pediatrics.

3. Hold the child in the ED until 7 am when relief arrives for the day shift.

4. Just bring the child up to the PICU.

5. Send the child home; it's just a fever.

Altruism says that the intensivist should go take a look. That would be best for the patient. It could improve the quality of the triage decision and optimize patient care.

Self-interest suggests options 2, 3, or 5 because the child is not the intensivist's immediate problem and addresses the intensivist's exhaustion.

So the professionalism issue here is altruism, “patient first,” but there is also the issue of financial overlay. The PICU provides expensive care and is a costly resource. A decision to admit to the PICU should not be made casually. General pediatrics may not be able to safely care for the patient, and a bad outcome means a lawsuit. Hospitalization should be avoided unless really necessary. It costs money. However, holding the patient in the ED is a dissatisfier and will damage the hospital in the eyes of the community.

Professionalism is a larger issue than merely resolving the “patient first” medical paradox, and it received a much more thorough examination in the late 1990s and first decade of the new millennium. Many of the groups that regulate medicine on physicians' behalf weighed in. Among them were the American Board of Internal Medicine Foundation, the American College of Physicians–American Society of Internal Medicine, and the European Federation of Internal Medicine, who worked together to draft the document *Medical Professionalism in the New Millennium: A Physician Charter*.[5]

Professionalism, the Physician Charter

The Charter adopted three principles and made 10 commitments to fulfill the medical profession's contract with society:

Principle 1: *Primacy of Patient Welfare*. Altruism demands that the patient's needs be given precedence over self-interest, market forces, societal pressure, and administrative exigency.

Principle 2: *Patient Autonomy*. Physicians must be honest with their patients and, whenever possible, empower them to make informed decisions.

Principle 3: *Social Justice*. There should be fair distribution of health care resources.

Commitment 1: *Professional Competence*. Each individual physician must assure his or her own, and the profession as a whole must assure its members', competence. Professionals are responsible for putting mechanisms in place to assure lifelong

learning and competence.

Commitment 2: *Honesty with Patients*. Patients must be completely and honestly informed. Medical errors must be acknowledged. Mistakes must be analyzed to improve the quality of health care.

Commitment 3: *Patient Confidentiality*. Patient trust demands that confidences be protected. Trust is essential to the doctor-patient (patient-doctor) relationship.

Commitment 4: *Appropriate Relations to Patients*. Patients are inherently vulnerable. Professionalism demands that they not be exploited.

Commitment 5: *Improve Quality of Care*. Physicians must not only maintain clinical competence but also work collaboratively to reduce medical errors, increase patient safety, minimize overuse of health care resources, and optimize outcomes of care.

Commitment 6: *Improve Access to Care*. Physicians must strive to reduce barriers to equitable health care and foster uniform and adequate standards of care.

Commitment 7: *Just Distribution of Finite Resources*. The physician must make wise and cost-effective use of limited resources.

Commitment 8: *Scientific Knowledge*. Where possible, care should be evidence based.

Commitment 9: *Manage Conflicts of Interest*. To maintain patient trust, physicians must recognize, disclose, and deal with conflicts of interest that arise in the course of their professional activities.

Commitment 10: *Assure the Integrity of Professional Responsibilities*. The profession must define, organize, and assure the standards of its current and future members.

The PICU as a Site for Medical Education and Lifelong Learning

The renaissance of interest in professionalism has created an endeavor to weave the topic into medical education, build it into curricula, and focus on it in coursework.[6] Despite that interest, medical student altruism, social interest, and other qualities of positive social value have been noted to decline as the student progresses through medical school and the early phase of clinical training.[7-11] The altruistic freshman is transformed by clinical experiences into the cynical senior. It has been argued that this growth of cynicism reflects the gap between what physicians say as teachers (the formal curriculum) and what physicians do as practitioners (the hidden curriculum).[12] When physicians do not "walk the talk," they plant the seeds of cynicism and nonprofessionalism.

For example: Dr. Blunt and an impressionable medical student are suturing in place a central line. Their patient is in a chemically induced coma, from self-medication, compounded by subsequent hypoxia. His story is tragic, and the student

knows that the teenager deserves sympathy and respect. As Dr. Blunt ties the last knot, she comments, “It would have been easier if he weren't so fat.” A lesson about sympathy and respect has gone array.

In the PICU, doctors, students, and nurses are compressed into a small, tense space. They are all engaged in lifelong learning as they play their separate roles in patient care. So, throughout their development and maturation as professionals, care providers in the PICU are continuously learning professionalism and cynicism from their colleagues.

All PICU care providers should clean up their acts, take care that their words and actions reflect the formal curriculum, fulfill their contract with society, and behave toward their patients as the professionals they set out to be.

CHAPTER 6

Nurses in Pediatric Critical Care

Patricia A. Moloney-Harmon, Martha A.Q. Curley

PEARLS

- Along with other members of the multidisciplinary team of dedicated intensive care experts, nursing navigates safe passage for patients and families during critical illness.
- Nurses coordinate the patient's and family's experiences by their continuous attention to the person who exists underneath all the advanced technology that is being employed.
- Building a humanistic environment that endorses parents as unique individuals capable of providing essential elements of care to their children constitutes the foundation for family-centered care.
- Caring practices include a constellation of nursing activities that are responsive to the uniqueness of the patient/family and create a compassionate and therapeutic environment with the aim of promoting comfort and preventing suffering.
- Excellence in a pediatric critical care unit is achieved through a combination of many factors and is highly dependent on a healthy work environment.
- Studies have demonstrated that a stable, established, and proficient nursing workforce improves patient outcomes.
- A successful critical care professional advancement program recognizes varying levels of staff nurse knowledge and expertise and fosters advancement through a wide range of clinical learning and professional development experiences.
- Technical training alone is insufficient for meeting patient and family needs in the critical care environment.

Pediatric critical care nursing has evolved tremendously over the years. The nurse plays a vitally important role in the pediatric intensive care unit (PICU) in fostering an environment in which critically unstable, highly vulnerable infants and children benefit from vigilant care and the highly coordinated actions of a skilled team of patient-focused health care professionals. Pediatric critical care nursing practice

encompasses staff nurses who provide direct patient care, nursing leaders who facilitate an environment of excellence, professional staff development that ensures continued nursing competence and professional growth, and nurse scientists who generate knowledge to support the practice of pediatric critical care nursing. This chapter discusses the essential components of pediatric critical care nursing practice.

Describing What Nurses Do: The Synergy Model

The Synergy Model describes nursing practice based on the needs and characteristics of patients and their families.[1] The fundamental premise of this model is that patient characteristics drive required nurse competencies. When patient characteristics and nurse competencies match and synergize, optimal patient outcomes result. The major components of the Synergy Model encompass patient characteristics of concern to nurses, nurse competencies important to the patient, and patient outcomes that result when patient characteristics and nurse competencies are in synergy.

Patient Characteristics of Concern to Nurses

Every patient and family member brings unique characteristics to the PICU experience. These characteristics—stability, complexity, predictability, resiliency, vulnerability, participation in decision making, participation in care, and resource availability—span the continuum of health and illness. Each characteristic is operationally defined as follows.

Stability refers to the person's ability to maintain a steady state (see also Chapter 81). Complexity is the intricate entanglement of two or more systems (eg, physiologic, family, and therapeutic). Predictability is a summative patient characteristic that allows the nurse to expect a certain trajectory of illness. Resiliency is the patient's capacity to return to a restorative level of functioning using compensatory and coping mechanisms. Vulnerability refers to an individual's susceptibility to actual or potential stressors that may adversely affect outcomes. Participation in decision making and participation in care are the extents to which the patient and family engage in decision making and in aspects of care, respectively. Resource availability refers to resources that the patient/family/community bring to a care situation and include personal, psychologic social, technical, and fiscal resources.

These eight characteristics apply to patients in all health care settings. This classification allows nurses to have a common language to describe patients that is meaningful to all care areas. For example, a critically ill infant in multisystem organ failure might be described as an individual who is unstable, highly complex, unpredictable, highly resilient, and vulnerable, whose family is able to become involved in decision making and care but has inadequate resource availability.

Each of these eight characteristics forms a continuum, and individuals fluctuate around different points along each continuum. For example, in the case of the critically ill infant in multisystem organ failure, stability can range from high to low, complexity from atypical to typical, predictability from uncertain to certain,

resiliency from minimal reserves to generous reserves, vulnerability from susceptible to safe, family participation in decision making and care from no capacity to full capacity, and resource availability from minimal to extensive. Compared with existing patient classification systems, these eight dimensions better describe the needs of patients that are of concern to nurses.

Nurse Competencies Important to Patients and Families

Nursing competencies, which are derived from the needs of patients, also are described in terms of essential continua: clinical judgment, clinical inquiry, caring practices, response to diversity, advocacy/moral agency, facilitation of learning, collaboration, and systems thinking.

Clinical judgment is clinical reasoning that includes clinical decision making, critical thinking, and a global grasp of the situation coupled with nursing skills acquired through a process of integrating formal and experiential knowledge. Clinical inquiry is the ongoing process of questioning and evaluating practice, providing informed practice on the basis of available data, and innovating through research and experiential learning. The nurse engages in clinical knowledge development to promote the best patient outcomes. Caring practices are a constellation of nursing activities that are responsive to the uniqueness of the patient/family and create a compassionate and therapeutic environment with the aim of promoting comfort and preventing suffering. Caring behaviors include, but are not limited to, vigilance, engagement, and responsiveness. Response to diversity is the sensitivity to recognize, appreciate, and incorporate differences into the provision of care. Differences may include, but are not limited to, individuality, cultural practices, spiritual beliefs, gender, race, ethnicity, disability, family configuration, lifestyle, socioeconomic status, age, values, and alternative care practices involving patients/families and members of the health care team. Advocacy/moral agency is defined as working on another's behalf and representing the concerns of the patient/family/community. For example, the nurse serves as a moral agent in identifying and helping to resolve ethical and clinical concerns within the clinical setting. Facilitation of learning is the ability to use the process of providing care as an opportunity to enhance the patient's and family's understanding of the disease process, its treatment, and its likely impact on the child and family. Collaboration is working with others (ie, patients, families, and health care providers) in a way that promotes and encourages each person's contributions toward achieving optimal and realistic patient goals. Collaboration involves intradisciplinary and interdisciplinary work with colleagues. Systems thinking is appreciating the care environment from a perspective that recognizes the holistic interrelationships that exist within and across health care systems.

These competencies illustrate a dynamic integration of knowledge, skills, experience, and attitudes needed to meet patients' needs and optimize patient outcomes. Nurses require competence within each domain at a level that meets the needs of their patient population. Logically, more compromised patients have more severe or complex needs; this in turn requires the nurse to possess a higher level of knowledge and skill in an associated continuum. For example, if a patient is stable but unpredictable, minimally resilient, and vulnerable, primary competencies of the nurse center on clinical judgment and caring practices (which include vigilance). If a

patient is vulnerable, unable to participate in decision making and care, and has inadequate resource availability, the primary competencies of the nurse focus on advocacy/moral agency, collaboration, and systems thinking. Although all the eight competencies are essential for contemporary nursing practice, each assumes more or less importance depending on a patient's characteristics. Optimal care is most likely when there is a match between patient needs/characteristics and nurse competencies.

Clinical Judgment

Clinical judgment—that is, skilled clinical knowledge, use of discretionary judgment, and the ability to integrate complex multisystem data and understand the expected trajectory of illness and human response to critical illness—defines competent nursing practice. In critical care, the novice nurse focuses on individual aspects of the patient and the environment. As expertise develops, the nurse develops a global understanding of the situation. The expert nurse is much better able to anticipate the needs of patients, predict the patient's trajectory of illness, and forecast the patient's level of recovery. The best nursing care often is invisible, as it should be, because untoward effects and complications are prevented. Along with other members of the dedicated team of PICU health care professionals, nurses, when exhibiting all key nursing competencies, facilitate the safest passage for patients and families through critical illness. Safe passage may include helping the patient and family move toward a greater level of self-awareness, knowledge, or health; transition through the acute care environment or stressful events; or a peaceful death.

Clinical Inquiry

Clinical inquiry optimizes the delivery of evidence-based care. Studying the clinical effectiveness of care and how it influences patient outcomes provides information that helps balance cost and quality. Quality improvement methods include use of multidisciplinary teams that work together to help systems operate in a way that promotes the best interests of patient care (see Chapter 11). Collaborative practice groups working with clinical practice guidelines (CPGs) provide the opportunity to initiate evidence-based and expert consensus-based interventions.

CPGs—that is, patient-centered multidisciplinary and multidimensional plans of care—help the team provide evidence-based practice and improve the process of care delivery. Effective CPGs are driven by patient needs and help provide evidence linking interventions to patient outcomes. Evidence-based guidelines can help to eliminate interventions that are steeped in tradition and opinion but do not actually benefit patients.

Caring Practices

Caring practices bring clinical judgment into view. Caring practices are activities that are meaningful to the patient and family and enhance their feelings that the health care team cares about them. Families equate caring behaviors with competent behaviors. Families trust that nurses will be vigilant. Vigilance, which includes alert and constant watchfulness, attentiveness, and reassuring presence, is essential to limit the complications associated with a patient's vulnerabilities.[1]

Nurses coordinate the patient's and family's experiences by their continuous

attention to the person who exists underneath all the advanced technology that is employed. This steady attention can make an important difference by helping patients and their families better tolerate the experience of critical illness. This aspect of practice, near continuous presence with patients, is unique to the profession of nursing.[1] For example, in working with patients with head injuries, caring nurses acknowledge the patients by surrounding them with their possessions, such as family pictures and cards from friends and their favorite music. Nurses talk with their unresponsive patients, orienting them and telling them what is going on, which preserves the patient's humanness. Occasionally a patient responds, as evidenced by an increase in heart rate or blood pressure, a decrease in intracranial pressure, or the shedding of a tear. Nurses take this level of communication one step further by teaching this process to family members so they too can interact with their critically ill loved one.

Pediatric and neonatal critical care nurses have provided leadership by integrating family-centered care into the practice of critical care. Building a humanistic environment that endorses parents as unique individuals capable of providing essential elements of care to their children lays the foundation for family-centered care. Family-centered care is more than just providing parents with unlimited access to their children.[1]

Nursing research ascertains that parents have the need for hope, information, and proximity; they must believe that their loved one is receiving the best care possible; and they seek the opportunity to be helpful, to be recognized as important, and to talk with other parents who have similar issues. Pediatric critical care nurses have gone beyond the identification of family needs to illustrating interventions that patients and families find helpful[1] and providing families with what they need to help their child. Parents believe the most important contribution pediatric critical care nurses make is to serve as the interpreter by translating their critically ill child's responses to others within the PICU environment.

Response to Diversity

Response to diversity honors the differences that exist among people and individuals. At a minimum, it requires that care be delivered in a nonjudgmental, nondiscriminatory manner. Effective communication with patients and families at their level of understanding may require customizing the health care culture to meet the diverse needs and strengths of families. Skilled nurses foresee differences and beliefs within the team and negotiate consensus in the best interest of the patient and family.

Advocacy/Moral Agency

Moral agency acknowledges the particular trust inherent within nurse-patient relationships, a trust gained from the nursing profession's long history of speaking on the patient's behalf in an effort to preserve a patient's *lifeworld* (Hooper, personal communication, 1996). The holistic view of the patient that nurses often possess is a reflection of moral awareness.

When a cure is no longer possible, nurses turn their focus to ensuring that death occurs with dignity and comfort. Nurses help “orchestrate” death by supporting parents and family members through the death of their loved one (see also Chapters

15 and 16). Nurses often coordinate the experience for patients and families when death is imminent.[2]

Pediatric critical care nurses support the practice of family presence during procedures and resuscitation. Including family members during pediatric resuscitation is not a universal practice. However, a systematic review of family presence during resuscitation in the PICU supports the belief that parents who are able to be present are better able to adjust to their child's death and better able to cope.[3] Parents who were not able to stay described more anguish. Local guidelines and education have been developed to facilitate parental presence during resuscitation. Importantly, physicians and nurses report increased comfort with parental presence when they, the professionals, are prepared to help support parent presence.[4]

Facilitation of Learning

Nurses facilitate learning so that patients and their families can become knowledgeable about the health care system and make informed choices. Teaching is an almost continuous process that involves helping the patient and family understand the critical care environment and therapies involved in critical care. Also essential is reinforcement of the patient's experience and how, most likely, the infant or child will cope with the ICU experience. This education provides patients with the capacity to help themselves manage the experience and for parents to help their infants and children.

Collaboration

Collaboration requires commitment by the entire multidisciplinary team. A classic study by Knaus and associates[5] found an inverse relationship between actual and predicted patient mortality and the degree of interaction and coordination of multidisciplinary intensive care teams. Hospitals with good collaboration and a lower mortality rate had a comprehensive nursing educational support program that included a clinical nurse specialist and clinical protocols that staff nurses can independently initiate. A study published in 2015 examined the relationship between nurse-physician collaboration and the development of hospital-acquired infections in critically ill adults. These results demonstrated that nurse-physician collaboration was inversely related to the incidence of ventilator-associated pneumonia and central line–associated infections.[6]

Systems Thinking

Nurses are constantly challenged to design, implement, and evaluate whole programs of care, manage units where programs of care are provided, and determine whether the health care system is meeting patient needs.[7] These vital components require a patient-centered culture that stresses strong leadership, coordination of activities, continuous multidisciplinary communication, open collaborative problem solving, and conflict management.[8] For many years nurses have learned to manipulate the system on behalf of their patients; however, systems thinking[9]—that is, the ability to understand and effectively manipulate the complicated relationships involved in complex problem solving—is a new but necessary skill in taking overall responsibility for the caregiving environment.

Managing complex systems is essential to creating a safe environment. Nurse-patient relationships commonly occur around transitional periods of instability brought about by the demands of the health care situation. Helping patients make transitions between elements of the health care system—for example, into and out of the community, or even into and out of the PICU—requires systems knowledge and intradisciplinary collaboration.

Optimal Patient Outcomes

According to the Synergy Model, optimal patient outcomes result when patient characteristics and nurse competencies synergize. A *nurse-sensitive outcome,* a term first coined by Johnson and McCloskey,[10] defines a dynamic patient or family caregiver state, condition, or perception that is responsive to nursing interventions. Brooten and Naylor[11] noted, "The current search for 'nurse-sensitive patient outcomes' should be tempered in the reality that nurses do not care for patients in isolation and patients do not exist in isolation." Outcomes have been described at three levels: patient, provider, and system.

Patient-Level Outcomes

Major patient-level outcomes of concern to pediatric critical care nurses include hemodynamic stability and the presence or absence of complications. Outcomes related to limiting iatrogenic injury and complications of therapy demonstrate the potential hazards present in illness and in the critical care environment. Patient/family satisfaction ratings are subjective measures of health or the quality of health services. Patient satisfaction measures involving nursing care typically include technical/professional factors, trusting relationships, and education experiences. Patient-perceived functional status and quality of life are multidisciplinary outcome measures. Linking patient satisfaction, functional status, and quality of life is important because the three factors often are related.

Provider-Level Outcomes

Provider-level outcomes include the extent to which care/treatment objectives are attained within a predicted time period. For example, providers are frequently interested in minimizing the duration of shock and organ dysfunction in general. Nurses coordinate the day-to-day efforts of the entire multidisciplinary team. The nurse's role as the coordinator of numerous services is essential for optimal patient outcomes and shorter lengths of stay. As discussed, nurse-physician collaboration and positive interaction is associated with lower mortality rates, high patient satisfaction with care, and low hospital-acquired complications.[5,6]

System-Level Outcomes

Critical care units must manage resources and maintain quality as collaboratively defined by both users and providers in the system. The goal is high-quality care at appropriate cost for the greatest number of people who need it. Important patient-system outcome data include recidivism and costs/resource utilization. Recidivism—that is, readmission—is repeated work that adds to the personal and financial burden of receiving/requiring and providing care. In addition to patient and system

factors, nurses can decrease the patient's length of stay through coordination of care, prevention of complications, timely discharge planning, and appropriate referral to community resources. Reducing length of stay while tracking emergency department visits and rehospitalization helps to ensure that cost shifting is not occurring.

Nightingale Metrics

One population-specific approach to measurement of nurse-sensitive outcomes is the Nightingale Metrics.[12] This program was developed so that bedside nurses could be actively involved in identifying nurse-sensitive metrics important to their unique patient and family practice. Nurses give care in an environment that should support the capacity of the patient and family to heal. In addition to supportive care, a large aspect of nursing is preventive care that often is not measured; thus care is often invisible. When measuring outcomes, it is important to account for the invisible aspects of nursing that have a tremendous impact on patients. This might include steps taken, according to the best understanding of what works, to prevent a particular complication. For example, invisible are the large numbers of pressure ulcers that never develop because of good nursing care. The Nightingale Metrics reflect current standards of care, are based on evidence, and are measurable (Box 6.1).

Box 6.1

Pediatric Intensive Care Unit: Example of Nightingale Metrics

- State Behavioral Scale (SBS) scores every 4 hours
- In patients with a central venous line, changing the dressing every 7 days
- Development of an enteral feeding guideline
- Mouth care every 4 hours
- Venous thromboembolism (VTE): Risk factors, central line removal, prophylactic medications
- Parental presence
- Pressure ulcer bundle: If patient is immobile, documentation of position change every 2 hours and positioning of heels off the bed; if not on bed rest, documentation of patient being out of bed or held in parent's or nurses' arms in previous 24 hours
- Ventilator-associated pneumonia bundle: Head of bed elevation at 30 to 45 degrees; documentation of oral hygiene twice in 24 hours; peptic ulcer prophylaxis (in patients not receiving tube feedings); discussion of extubation readiness test on rounds; daily holiday from sedation or chemical paralysis

- “Time to critical intervention”: response to panic laboratory value, the time intervals from sending specimen to laboratory to first intervention to correct laboratory value

Leadership

Excellence in a pediatric critical care unit is achieved through a combination of many factors and is highly dependent on effective leadership.[13] Numerous studies have demonstrated the importance of leadership in creating an environment where both nurses and patients can flourish.

Specialized units such as PICUs require staff with the expert knowledge and skill required to meet the multifaceted needs of patients and families. A healthy work environment should improve retention and recruitment. An evidence-based practice working group at one facility piloted several leadership proposals to enrich the nursing work environment. The criteria instituted by the American Association of Critical Care Nurses Standards for Establishing and Sustaining Healthy Work Environments—which include skilled communication, true collaboration, effective decision making, appropriate staffing, meaningful recognition, and authentic leadership—were the basis for the proposals. When these standards were integrated with qualities of the staff such as clinical proficiency, personal values, and management experience, the results showed improvement in absenteeism, patient and staff satisfaction, and nursing quality indicators.[14]

The literature demonstrates that an established and proficient workforce improves patient outcomes. A study conducted by Aiken and colleagues[15] observed the effect of nurse staffing levels on patient outcomes and factors affecting nurse retention. A total of 10,184 nurses from 168 hospitals were surveyed. After adjusting for patient and hospital characteristics, each additional patient per nurse was associated with a 7% increase in the likelihood of dying within 30 days of admission and a 7% increase in the odds of failure to rescue (death subsequent to a complication that develops during the hospital stay). In addition, after adjusting for nurse and hospital characteristics, each additional patient per nurse was associated with a 23% increase in the odds of burnout and a 15% increase in the odds of job dissatisfaction.

Aiken and colleagues[16] have continued their work by assessing the net effects of work environments on nurse and patient outcomes. Using data from the same hospitals and nurses, they investigated whether better work environments were related to lower patient mortality and better nurse outcomes independent of nurse staffing and the education of the registered nurse workforce in hospitals.[16] Work environments were evaluated according to the practice environment scales of the Nursing Work Index. Three of the five subscales studied were nursing foundations for quality of care; nurse manager ability, leadership, and support; and collegial registered nurse/physician relationships. Outcomes studied included job satisfaction, burnout, intent to leave, quality of care, mortality, and failure to rescue. They found that a greater percentage of nurses working in hospitals with unsupportive care environments reported higher burnout levels and dissatisfaction with jobs. They also found that work environment had a significant effect on nurses' plans to leave their units. When all patient and nurse factors were taken into account, the likelihood of patients dying within 30 days of admission was 14% lower in hospitals with healthier care environments. These findings support the observation that nursing

leaders have at least three major opportunities to boost nurse retention and patient outcomes. These opportunities include increasing nurse staffing, using a more highly educated nurse workforce, and enhancing the work environment.

Work conducted by the same investigators validated their previous findings. An observational study using discharge data for 422,730 patients aged 50 years or older who underwent common surgeries in 300 hospitals in nine European countries demonstrated that an increase in a nurses' workload boosted the probability of inpatient mortality by 7%. In addition, a greater number of nurses with bachelor's degrees was associated with a 7% lower risk of mortality.[17]

One of the best examples of a work environment that champions the nurse at the bedside is the magnet hospital designation. Data demonstrate that hospitals that use the structure for magnet designation achieve significant improvements in their work environments.[16] Hospitals that have even some of the magnet characteristics illustrate improved nurse and patient outcomes. Characteristics of magnet hospitals that have the most impact on nurse and patient outcomes are investments in staff development, superior management, frontline manager supervisory skill, and good nurse/physician collaboration.[16]

Nurses who work in magnet hospitals do identify their environments as healthy. A study of 12,233 nurses confirmed healthy work environments in 82% of 540 clinical units and provided evidence that applying structures that support inter- and intradisciplinary collaboration and decision making promote the development of healthy work environments.[18] The importance of a healthy work environment cannot be stressed enough as the means to ensure a viable, competent, and caring workforce. Nurses look for a culture that respects the nurse's experience, skills, abilities, and unique contributions.

Beacon Award

The Beacon Award for Critical Care Excellence, created by the American Association of Critical-Care Nurses (AACN), distinguishes adult critical care, adult progressive care, and pediatric critical care units that attain high-quality outcomes. This prestigious award provides the critical care community with a means of recognizing achievements in professional practice, patient outcomes, and the health of the work environment.

A pediatric critical care unit can achieve the Beacon Award by meeting several criteria in the areas of recruitment and retention; education, training, and mentoring; evidence-based practice and research; patient outcomes; healing environment; and leadership and organizational ethics. Together these characteristics provide a comprehensive view of any given ICU. To date, 25 pediatric critical care units have received the Beacon Award for Critical Care Excellence (M. Sanchez, personal communication, 2015).

Professional Development

A critical aspect of development for the nurse is the ability to advance and be recognized professionally. A successful critical care professional advancement program recognizes varying levels of staff nurse knowledge and expertise and fosters advancement through a wide range of clinical learning and professional

development experiences. Essential components of this program include an orientation program, a continuing education plan, and an array of other opportunities for clinical and professional development. Unit-based advancement programs are most effective when they are linked to the nursing department's professional advancement program.

A professional advancement program that recognizes and rewards evolving expertise contains elements of both clinical and professional development strategies. The Synergy Model's ability to describe a patient-nurse relationship that optimizes patient and family outcomes illuminates the various dimensions of critical care nursing practice that require attention from a development perspective.[1,19] The impact of these contributions can be measured based on the nurse's level of expertise, and professional development strategies can be focused to have an impact on patient care.

By combining the nurse competencies identified in the Synergy Model and the behaviors identified in Benner's levels of practice,[20] a continuum of expertise can be described that matches behavior with practice levels. It focuses recognition and reward on clinical practice. The impact of expert nurses on patient outcomes is presented in quantitative and financial terms that can be understood throughout the health care system. The model links clinical competencies to patient outcomes.

Nurses require a broad body of knowledge to meet patient and organizational needs. This requirement necessitates a lifelong process of professional development targeted to specific levels of clinical practice. Nurses can choose from many learning options, such as academic education, continuing education programs, participation in research, collaborative learning, case studies, and simulations. Nurses view the availability of continuing education, both as learning in the unit and in-service education, as very important.[21]

Staff Development

The goal of nursing staff development programs is safe, competent practice. Comprehensive programs provide the critical resources to support and promote practice. In addition, professional nursing standards of practice, health care laws, regulations, and accreditation requirements focus on the components of competent patient care to protect the health care consumer. The establishment of a staff development program that is linked to clinical practice is key to the success of professional nurse development.

Technical training alone is no longer sufficient to meet the care delivery needs of the nurse in the critical care environment. In addition to knowledge about disease processes and physiologic instability associated with them, critical care nurses require broad knowledge and expertise in areas such as communication, critical thinking, and collaboration.[8] They need to attain the diverse skills necessary to meet the complex needs of their patients and families.

The theory and science required to meet the synergy competencies include topics such as specific disease processes, nursing procedures, cultural awareness, moral and ethical principles and reasoning, research principles, and learning theories. This information can be presented using a variety of methods, including lectures, written information, posters, self-studies, or computer-based technology. However, it is essential that the information be related to realistic clinical situations. Clinical

scenarios, case studies, and simulations that represent the dynamic and ambiguous clinical situations nurses encounter daily are most effective.[21]

Bedside teaching is particularly helpful in the development of clinical judgment and caring practice skills. Expert nurses are role models of many of the competencies delineated by the Synergy Model. Novice nurses learn by watching these expert nurses and emulating their behaviors. Clinical teaching also enables the novice practitioner to gain experience with unfamiliar interventions in a safe and protected environment. Communicating and demonstrating clinical knowledge focuses learning, positively affects patient outcomes, and adds to the total body of nursing knowledge.[22]

Simulation-based learning has been incorporated with increased frequency into pediatric critical care nursing practice as a state-of-the-art educational approach. Simulation serves several purposes, such as enhancing patient safety, increasing clinical competence, and promoting effective teamwork. Simulation provides a nonthreatening environment where participants can integrate cognitive, psychomotor, and affective skill attainment without fear of hurting patients.[23]

Information about research and research use builds clinical inquiry and system thinking skills. Demystifying research, outcome, and quality processes contributes to the development of these key skills. The use of journal club formats and supporting staff involvement in research helps develop clinical inquiry skills. Building knowledge in the areas of health care trends and political action expands system thinking skills. The development of critical thinking skills and problem solving skills also assists with the development of system thinking.

Developing excellent communication skills is an essential part of nurses' professional development plans. In addition to their value in enhancing relationships with patients, families, and colleagues, good communication skills are critical for teaching less experienced staff. Presenting clinical teaching strategies and helping staff to determine learner readiness and to assess understanding will facilitate learning. The importance of developing patience, flexibility, and a nonconfrontational style is reinforced. Negotiation, conflict resolution, time management, communication, and team building are components of collaboration skills. Role playing, role modeling, and clinical narratives are methodologies that have been used to develop collaboration skills.

Nurses learn technical skills and scientific principles in many ways, but caring practices and advocacy are developed only through relationships that evolve over time.[20] Nurturing, professional relationships with experienced staff allow novices to integrate their evolving perspectives into practice. Expert nurses who share their clinical knowledge and coach other nurses have a tremendous impact on novice nurses. Nurses who coach do so because they are able to clinically persuade and guide less experienced staff in challenging situations. They demonstrate expert skills and expedite the ongoing clinical development of others.

A variety of staff development programs exist, but most fall into three general categories: orientation, in-service education, and continuing education programs.

Orientation

Orientation programs help acclimate new staff to unit-based policies, procedures, services, physical facilities, and role expectations in a work setting. A specific type of orientation that has developed in response to the nursing shortage is the critical care

internship program. These programs have been developed as a mechanism to recruit and train entry-level nurses. They are designed to integrate nurses with little or no nursing experience into the complex critical care environment. They provide extended clinical support for novice nurses and introduce new knowledge more deliberately than do traditional orientation programs. Basic information and skill acquisition are the core features of these programs. This foundation builds on the knowledge and skills acquired in nursing school programs. Teaching usually is under the direction of a hospital educator and generally involves less senior staff members as preceptors. Typically, the novice nurse starts with providing care to the least complex patients. The program establishes a foundation on which the novice can develop into a competent clinician.[24]

AACN has partnered with the Child Health Corporation of America to release the Essentials of Pediatric Critical Care Orientation program. This program provides a bridge for the knowledge gap between what nurses learn in their basic education program and what they need to know in order to achieve initial clinical competence with critically ill pediatric patients. The program consists of an interactive eight-module course that provides case scenarios and practice activities that augment knowledge and improve job satisfaction. This program provides flexibility because it is a self-paced didactic e-learning course that can be incorporated into a blended learning environment that combines traditional educational activities such as preceptorships, discussion groups, workshops, and simulation experiences.

In-Service Education

In-service education programs, which are the most frequent type of staff development activity, involve workplace learning experiences that help staff to perform assigned functions and maintain competency.[21] These programs usually are informal and narrow in scope. They often are spontaneous sessions resulting from new situations on the unit in settings such as patient rounds or staff meetings. Examples of planned in-service sessions are demonstrations of new equipment, procedure reviews, and patient care conferences.

Continuing Education

New medical developments, legislation, regulations, professional standards, and expectations of health care consumers help determine the need for continuing education. Continuing nursing education includes planned, organized learning experiences designed to expand knowledge and skills beyond the level of basic education.[21] The focus is on knowledge and skills that are not specific to one institution and that build on previously acquired knowledge and skills. Examples of continuing education programs include formal conferences, seminars, workshops, and courses.

Certification in Pediatric Critical Care Nursing

In 1975, the AACN Certification Corporation was established to formally recognize the professional competence of critical care nurses. The mission of the AACN Certification Corporation is to certify and promote critical care nursing practice that optimally contributes to desired patient outcomes. The program establishes the body of knowledge necessary for critical care registered nurse (CCRN) certification, tests

the common body of knowledge needed to function effectively within the critical care setting, recognizes professional competence by granting CCRN status to successful certification candidates, and assists and promotes the continual professional development of critical care nurses.

In 1997 the unique competencies of pediatric, neonatal, and adult critical care nurses were rearticulated using the Synergy Model[1] as a conceptual framework. AACN has published the new test plan (Table 6.1). To date more than 4000 pediatric critical care nurses hold CCRN–Pediatric certification (C. Hartigan, personal communication, 2015), and more than 50 hold the Pediatric CCRN-K credential. This is the new knowledge-based CCRN credential for nursing professionals who do not work at the bedside but apply knowledge in a way that enhances the positive impact of patients, nurses, or organizations on acutely or critically ill adult, pediatric, or neonatal patients. CCRN-K certification may be obtained by completing an initial exam or as a renewal option for CCRN and CCRN-E (Tele-ICU Acute/Critical Care Nursing) certificants who no longer do traditional bedside care. AACN also provides clinical nurse specialist certifications in pediatric critical care.

TABLE 6.1

Pediatric Critical Care Registered Nurse Test Plan

I. Clinical Judgment (80%)
A. Cardiovascular (14%)
1. Acute pulmonary edema
2. Cardiac surgery (eg, Norwood, Blalock-Taussig shunt, tetralogy of Fallot repair, arterial switch)
3. Cardiogenic shock
4. Cardiomyopathies (eg, hypertrophic, dilated, restrictive, idiopathic)
5. Dysrhythmias
6. Heart failure
7. Hypovolemic shock
8. Interventional cardiology (eg, catheterization)
9. Myocardial conduction system defects
10. Structural heart defects (acquired and congenital, including valvular disease)
B. Pulmonary (18%)
1. Acute lung injury (eg, acute respiratory distress syndrome, respiratory distress syndrome)
2. Acute pulmonary embolus
3. Acute respiratory failure
4. Acute respiratory infections (eg, acute pneumonia, croup, bronchiolitis)
5. Air leak syndromes (eg, pneumothorax, pneumopericardium)
6. Aspiration (eg, aspiration pneumonia, foreign body, meconium)
7. Asthma, chronic bronchitis
8. Bronchopulmonary dysplasia
9. Congenital anomalies (eg, diaphragmatic hernia, tracheoesophageal fistula, choanal atresia, pulmonary hypoplasia, tracheal malacia, tracheal stenosis)
10. Pulmonary hypertension
11. Status asthmaticus
12. Thoracic surgery
13. Thoracic trauma (eg, fractured ribs, lung contusions, tracheal perforation)
C. Endocrine (5%)
1. Acute hypoglycemia
2. Diabetes insipidus
3. Diabetic ketoacidosis
4. Inborn errors of metabolism
5. Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
D. Hematology/Immunology (3%)
1. Coagulopathies (eg, idiopathic thrombocytopenic purpura, disseminated intravascular coagulation, heparin-induced thrombocytopenia)
2. Oncologic complications
E. Neurology (14%)
1. Acute spinal cord injury
2. Brain death (irreversible cessation of whole brain function)
3. Congenital neurologic abnormalities (eg, myelomeningocele, encephalocele, atrioventricular malformation)

4. Encephalopathy (eg, anoxic, hypoxic-ischemic, metabolic, infectious) 5. Head trauma (eg, blunt, penetrating, skull fractures) 6. Hydrocephalus 7. Intracranial hemorrhage/intraventricular hemorrhage (eg, subarachnoid, epidural, subdural) 8. Neurologic infectious disease (eg, congenital, viral, bacterial) 9. Neuromuscular disorders (eg, muscular dystrophy, Guillain-Barré syndrome, myasthenia gravis) 10. Neurosurgery 11. Seizure disorders 12. Space-occupying lesions (eg, brain tumors) 13. Spinal fusion 14. Stroke (eg, ischemic, hemorrhagic)
F. Gastrointestinal (6%)
1. Acute abdominal trauma 2. Acute gastrointestinal hemorrhage 3. Bowel infarction/obstruction/perforation (eg, necrotizing enterocolitis, mesenteric ischemia, adhesions) 4. Gastroesophageal reflux 5. Gastrointestinal abnormalities (eg, omphalocele, gastroschisis, volvulus, Hirschsprung disease, malrotation, intussusception) 6. Gastrointestinal surgeries 7. Hepatic failure/coma (eg, portal hypertension, cirrhosis, esophageal varices, biliary atresia) 8. Malnutrition and malabsorption
G. Renal (6%)
1. Acute renal failure 2. Chronic renal failure 3. Life-threatening electrolyte imbalances
H. Multisystem (11%)
1. Asphyxia 2. Distributive shock (eg, anaphylaxis) 3. Hemolytic uremic syndrome 4. Multiorgan dysfunction syndrome (MODS) 5. Multisystem trauma 6. Near drowning 7. Sepsis/septic shock 8. Systemic inflammatory response syndrome (SIRS) 9. Toxic ingestions/inhalations (eg, drug/alcohol overdose) 10. Toxin/drug exposure
I. Behavioral/Psychosocial (3%)
1. Abuse/neglect 2. Developmental delays 3. Failure to thrive
II. Professional Caring and Ethical Practice (20%)
A. Advocacy/Moral Agency (2%)
B. Caring Practices (4%)
C. Collaboration (4%)
D. Systems Thinking (2%)
E. Response to Diversity (2%)
F. Clinical Inquiry (2%)
G. Facilitation of Learning (4%)

Data from Pediatric CCRN Test Plan, Aliso Viejo, CA, 2015, American Association of Critical-Care Nurses.

Nursing Research

Pediatric critical care nursing is a science as well as an art. It is vital that nursing interventions supporting the care of the critically ill child and his or her family be grounded in high-quality evidence generated though pediatric-specific research. Whereas knowledge generated in the larger neonatal and adult populations can inform pediatric practice, the developmental and maturational differences in our unique patient population may require independent study. A group of nurse scientists convened to summarize the state of the science in pediatric critical care nursing and to prioritize a list of nursing research topics for future focus. The group identified four top research priorities as described in Table 6.2.[25]

TABLE 6.2

Four Top Research Priorities Identified by Nurse Scientists in Pediatric Critical Care Nursing

1. Facing death: end-of-life care and decision making: What nursing interventions directly impact the child and family's experience during withdrawal of support in the PICU?
2. Caring for patient's families: Evaluate the long-term psychosocial impact of a child's critical illness on family outcomes.
3. Making a case: Communicating clinical assessments and improving teamwork: Can effective team communication models improve patient and family outcomes in pediatric critical care?
4. Diagnosing and managing life-sustaining physiologic functions: Articulate core nursing competencies that prevent unstable situations from deteriorating into crises in pediatric critical care.

From Tume LN, Coetzee M, Dryden-Palmer K, et al. Pediatric critical care nursing research priorities—initiating international dialogue. Pediatr Crit Care Med. 2015;16:e174-182.

Summary

Pediatric critical care nursing has evolved into a specialty in its own right. Pediatric critical care nurses make significant and unique contributions to the health care of children. A pediatric critical care nurse requires knowledge and skills in both the art and science of nursing. A supportive, empowered environment and support for professional advancement are essential to the development of knowledge and skills.

CHAPTER 7

Research in Pediatric Critical Care

Robinder G. Khemani, Martha A.Q. Curley

PEARLS

- Pediatric critical care is an ideal venue for research because of the rapid progression of disease and resulting ability to observe change, few comorbid conditions compared with adult critical care, the breadth of subspecialty care, the developmental spectrum, abundant existing data, the interprofessional nature of PICUs, and a collaborative research infrastructure.
- Pediatric critical care research is challenged by limited understanding of the interplay between development and critical illness, imprecise short-term outcomes, limited bench-to-bedside translations, perceptions of cherry-picking good ideas from adults rather than generating novel ideas, the complex interaction between the evolution of disease and management, the relative value of research in our specialty, and variability in management.
- Opportunities for growth of pediatric critical care research lie in big data and informatics, precision science approaches, novel medical devices designed with children in mind, and adaptive methods in clinical trials.
- The future of pediatric critical care research is threatened by limited extramural funding, the academic focus of discovery, confusion about the role of our specialty, segmentation of the pediatric critical care market, consent rates for pediatric studies, and the perception of a "small pediatric market."

Strengths, Weaknesses, Opportunities, and Threats to Pediatric Critical Care Research

Pediatric critical care research is at an exciting crossroad. There has been tremendous growth in the number of investigators engaging in research related to pediatric critical care, with an increasing number of high-impact discoveries and publications.[1-5] While there has historically been a divide between clinical and laboratory research, the bench-to-bedside to bench translational models have

enabled modern scientists to bring breakthrough understanding to the care of critical illness. It is now common that pediatric critical care researchers have "feet" in both domains or collaborate extensively with others outside their own domain.

This chapter is meant to describe the current state of pediatric critical care research. Using a strengths, weaknesses, opportunities, and threats (SWOT) approach, we highlight the factors related to conducting clinical research in our subspecialty. The following sections are in no way exhaustive; instead, they highlight broad areas and issues related to pediatric critical care research.

Strengths of Pediatric Critical Care Research

Many factors make pediatric critical care an ideal venue for research and discovery. These include the rapid progression of disease and resulting ability to determine the impact of experimental measures, few comorbid conditions compared with adult critical care, the breadth of subspecialty care, the developmental spectrum, abundant existing data, the interprofessional nature of pediatric ICUs (PICUs), and a collaborative research infrastructure.

Rapid Progression of Disease and Short-Term Outcomes

A distinct advantage of critical care research in general is that patient response to treatment can be measured quickly. Frequently, the critical phase of disease evolves over minutes or days, rather than months or years. Therapeautic decisions often have an immediate, measurable, physiologic response. Although short-term improvements in physiology may not impact long-term outcomes,[3,4,6-15] the immediate changes have led to fundamental discoveries to better understand the pathophysiology and develop new therapies. Some of the early discoveries regarding cardiopulmonary interactions and pulmonary hypertension, which are crucial for management of ventilated patients, for example, were derived from studies on children or animal models of pediatric disease.[16-21]

Moreover, while there is a growing evidence about the long-term impact of ICU management, many therapies have immediate impact on short-term outcomes like mortality, length of mechanical ventilation, length of ICU or hospital stay, and functional status at ICU or hospital discharge.[22,23] In general, clinical research studies in critical care are less subject to loss of patients to follow-up. These characteristics have helped advance clinical care through more detailed understanding of, for example, the importance of early goal-directed therapy for sepsis,[24] timely administration of antibiotics for septic shock,[25] and mechanical ventilation strategies and adjuvant therapies for patients with acute respiratory distress syndrome (ARDS).[9,26] Although the rapidity of the disease states leads to some advantages, particularly with regards to measuring short-term outcomes, it introduces a set of challenges regarding timing of interventions (see weakness later), which may partially explain negative trials in pediatric critical care.

Fewer Comorbid Conditions

Management of critically ill patients is a complex interplay between the severity and

evolution of acute critical illness and a patient's usual health status. Two critically ill children with similar etiology and initial severity of pediatric acute respiratory distress syndrome (PARDS) may have markedly different outcomes based on the presence or absence of preexisting chronic lung disease or immunodeficiency.[3,27] Chronic illness is a major consideration in pediatric critical care, with recent estimates that over 50% of all PICU patients have complex chronic conditions on admission to the PICU, which are associated with higher severity of illness-adjusted mortality.[28] However, these rates are still significantly lower than those published in adults (65%–80%).[29] Furthermore, the current landscape of many adult ICUs has an increasing number of elderly and extremely elderly patients, who have stepwise increases in mortality risk as a function of age.

Although higher mortality rates in adult critical care may allow the use of mortality as a viable outcome variable in adult critical care research, preexisting comorbidities make it difficult to test the efficacy of new therapeutic interventions. For example, severity of illness is a less robust predictor of outcome in adults than in children. This finding is highlighted in the ARDS literature, where markers of oxygenation are more clearly associated with mortality in pediatric ARDS than in adult ARDS.[30-32] While death from ARDS in both adults and children is frequently from multiple organ failure, and not refractory hypoxemia, the hypoxemia metrics likely capture the severity of the initial insult, as well as the inflammatory response seen in ARDS. This common response may ultimately explain the development of multiple organ dysfunction that leads to death in both adult and pediatric ARDS. The presence of preexisting comorbidities modifies this response, as a less severe insult in an elderly patient or someone with immunodeficiency may be more likely to result in death than the same insult in a previously healthy individual. Furthermore, the presence of multiple comorbidities amid a lifetime of chronic illness confounds the potential benefits of therapeutic interventions. Even reversal of the acute pathophysiology with a therapy does not reverse the progressive organ dysfunction because previous insults to those organs from a lifetime of chronic disease prevent recovery.

Pediatric Intensive Care Clinicians as Generalists

The modern era of pediatric critical care training mandates general pediatric training first. Although there has been some separation into specialty ICUs (eg, cardiac, neurologic), patients in most PICUs represent nearly every pediatric specialty and subspecialty. The range of disorders facilitates transfer of knowledge and discovery and encourages collaborative relationships among specialties. Hence, pediatric critical care research can be disease or organ specific, with partnership with subspecialists. It is through such collaborative relationships, for example, that the importance of acute kidney injury and the utility of renal replacement therapy have come to the forefront of research in recent years. This has led to the development of standardized criteria to define kidney injury, a wealth of new methodologies and equipment for renal replacement services applicable for the smallest children, and overall improvements in mortality and morbidity for children who develop kidney injury.[33-42] Similar results are seen in the realm of neurocritical care, with partnerships among intensivists, neurologists, and neurosurgeons to develop, test, and implement more advanced neuro-monitoring techniques and treatments.

Developmental Spectrum

A distinct challenge but also a strength of pediatric critical care research stems from the age and development spectrum seen in PICUs. Pulmonary and cardiac physiology, for example, change as a function of age and maturation. Although there is no clear population-based cut point at which a child becomes an adult, lung growth and development are often complete by the time the child reaches adult height.[43,44] As a consequence, the development of new research techniques related to respiratory support or monitoring can be developed in the PICU, tested on adolescents, and translated to adults. The opposite may be more problematic, as devices developed for adults are often difficult to scale to pediatrics. Even modern pulmonary function equipment, which is standard in many adult ICUs or pulmonary function laboratories, will not work on young children who are unable to cooperate with the testing process. Moreover, the size of the device (eg, the dead space of many pneumotachometers) potentially leads to physiologic instability in pediatric patients. On the other hand, if children form the basis for the creation of a technique to measure lung volumes, in which careful attention is paid to overcoming developmental or size-based limitations, these techniques can be successfully used immediately in adults, even in those who are not cooperative.[45-47]

Several commonly used therapies have been developed for use in critically ill children and subsequently applied to adults. Surfactant was developed for, and has had dramatic impact on, premature infants and has been the subject of numerous trials in adult and pediatric ARDS, albeit with generally negative benefit to date. High-frequency oscillatory ventilation (HFOV) was developed in children, and although recent adult trials have curbed the enthusiasm of the applicability of HFOV for the early management of adult ARDS,[48,49] HFOV is still applicable and often used for adults with severe ARDS. Finally, the cystic fibrosis (CF) drug Kalydeco (Ivacaftor), which targets the underlying protein defect in CF for patients with the G551D mutation, underwent its first phase III clinical trial in patients 12 years of age and older and demonstrated significant sustained improvement in short-term lung function, nutrition, and fewer pulmonary exacerbations.[50] These studies, admittedly involving children most similar to adults, but without the consequences of longer-standing disease, introduced a new paradigm in CF research targeting drug development specific for the genetic mutations responsible for the disease, with more personalized approaches to therapies.

Wealth of Existing Data to Analyze

Critical care research benefits from the large amount of existing medical data available for secondary analysis. Electronic health care records and monitoring systems in modern ICUs allow storage and potentially ready access to large amounts of physiologic data. Although one needs to be cautious regarding the quality of data stored with inadequate annotation of important clinical events, important associations among physiologic events, treatments, and outcomes can be identified. Advancements in statistical and machine learning techniques have refined our ability to use these data in meaningful ways (see also Chapter 12).

The degree of granularity of existing data often dictates its usefulness for answering specific questions.[51] Many datasets created for other purposes, such as claims or billing, quality improvement, and other research studies, can be accessed

for secondary analysis. The accessibility and cost varies, but these resources offer the opportunity for investigators to determine the existing process of care or examine the strength of the association between a variable of interest and a given outcome before engaging in subsequent studies,[52] generate hypotheses, or engage in predictive modeling. Moreover, with advancements in statistical techniques, it is possible to link deidentified databases using probabilistic models, without violating any issues related to patient privacy. Observational data have been key to developing and refining of global and disease-specific severity of illness scores and characterizing variables associated with outcome for critically ill children with head injury, asthma, acute respiratory distress syndrome, sepsis, and trauma, among others.[53-57] Existing data can also help monitor the postmarketing surveillance of new drugs, identifying higher rates of intussusception from certain types of rotavirus vaccination.[58] Moreover, reanalysis of existing data has led to the development of more advanced and new developments in critical care monitoring, which can improve short-term morbidity or mortality.[59]

Interprofessional Care

Intensive care research, particularly in pediatrics, benefits from the interprofessional nature of the care team. Each critically ill child interacts with a multitude of intensive care clinicians (physicians, nurses, respiratory therapists, pharmacists, social workers, physical and occupational therapists, nutritionists, etc). Pediatric critical care has embraced a team-based approach for patient care, which facilitates research. This multidisciplinary team approach introduces new lines of research that may target aspects of the patient experience and morbidity not often considered when clinicians remain in their disciplinary silos. These interprofessional collaborations have led to some of the most innovative research in pediatric critical care, highlighting the importance that each of these disciplines has on the science of critical care, and developing methods to improve outcomes for children.[1,2,4,60-63] In many ways, pediatric critical care has taken the lead in knowledge development related to the importance of interprofessional care for the critically ill patient.

Collaborative Research Networks

Pediatric critical care is advantaged by collaborative research. There are now several research networks in place. Some research networks do not have funding but provide a vehicle for investigators to have their science reviewed critically and enlist collaborating sites that have some existing research infrastructure. The Pediatric Acute Lung Injury and Sepsis Investigator (PALISI) network[27] is an example of such a network. With the benefit of PALISI networking, numerous investigators have been able to secure extramural funding for large clinical trials or simply get a group of collaborating institutions together to voluntarily conduct unfunded but important research. The list of publications from networks like PALISI continues to grow, and the organization provides opportunities for the training and future development of pediatric critical care researchers. Similar collaborative research networks exist internationally and have pediatric sections, including the Canadian Critical Care Trials Group (CCCTG), the Australian and New Zealand Intensive Care Society (ANZICS), and the European Society of Pediatric and Neonatal Intensive Care (ESPNIC).[27] Other research networks have resources available for conducting

research projects, but participation is often limited on the basis of competitive applications. Such an example is the National Institutes of Health[64] Collaborative Pediatric Critical Care Research Network (CPCCRN).[65]

Weaknesses of Pediatric Critical Care Research

While there is much strength in the current state of pediatric critical care research, some of the same strengths can be perceived as weaknesses. Some of these weaknesses relate to the complex interplay between development and critical illness, challenges with short-term outcomes, limited bench-to-bedside translations, perceptions of cherry-picking good ideas from adults rather than generating novel ideas, the complex interplay between the evolution of disease and management, the relative value of research in our specialty, and variability in management with lack of equipoise.

Patient Development Intersecting With Critical Illness

While the age spectrum of critically ill children in PICUs can be a strength when translating findings back to adults, the complex interplay between the pathophysiology of critical illness and age (eg, developmental process, immune response, epidemiology of diseases) complicates research. Researchers have to consider age-based stratifications, as the expected response to therapies or pathophysiology may be different in the infant compared with the older child or adolescent. A simple example relates to normalization of vital signs for severity of illness scoring, where a heart rate of 120 may be normal in an infant but abnormal in an adolescent. More complicated examples relate to potential differences in response to therapy as a function of age, such as prone positioning for ARDS, where age may be an imperfect surrogate for chest wall elastance, which may ultimately influence the recruitabilty of the lung when turning a patient from the supine to prone position.[4,10] Furthermore, the risks of some therapies may be quite different across the age spectrum. For example, administration of surfactant to an infant with ARDS may be easier (less volume to distribute, easier to position the patient to get more equal distribution throughout the lung) than to a 70-kg adolescent. This heterogeneity in potential treatment effect (based on age or other factors) ultimately affects the design of clinical trials, requiring alternative types of randomization or stratification a priori, or planned subgroup analysis.

There are also differences in disease etiology and epidemiology for which age is an imperfect surrogate. For example, a subdural hematoma in a 3-month-old with inflicted trauma secondary to child abuse is very different from a subdural hematoma in a 13-year-old in a motor vehicle accident. Some studies report lower mortality rates for younger children with ARDS compared with older children.[66] There are multiple potential explanations for such observations including different clinical triggers for ARDS (higher incidence of respiratory viral infections in younger children), developmental responses to mechanical ventilation and different rates of ventilator-induced lung injury (VILI), and potentially different inflammatory responses.

Most research studies and clinical trials in pediatrics are designed to include a representative sample of the children, but the study protocols may need to be

different to account for these age and developmental differences, and ultimately subgroups may need to be considered to evaluate the risk-benefit profile as a function of age group. Moreover, the subgroupings can be somewhat arbitrary and need to be linked to the individual research question on the basis of the proposed relationship between age and the outcome and intervention being studied. This is an important limitation in pediatric critical care research.

Short-Term Outcomes

Over the past several decades, mortality rates for critically ill infants and children have decreased.[67,68] Although this speaks to the evolution of our specialty and translates into important benefits for our patients, mortality as a primary outcome measure in PICU clinical trials is now rarely useful because even some of the highest-risk diagnoses (eg, ARDS, septic shock) have mortality rates below 10%. A clinical trial would require enrollment of more than 2000 patients per arm to demonstrate a statistically significant 25% relative risk reduction in mortality.

Other patient-centered, clinically meaningful outcome measures such as residual morbidity affecting functional status and quality of life, as well as cost of care, are available, but clinical researchers frequently employ surrogate outcome measures such as length of stay, length of mechanical ventilation, ventilator-free days, new or progressive organ dysfunction, or organ failure–free days. Imprecision in measurement introduces potential for bias. For example, length-of-stay variables are subject to practice variation by providers or institutions and organ dysfunction variables may be subject to interpretation or incomplete data (eg, Glascow Coma Scale). Moreover, there has been a trend to create composite variables like ventilator-free days (ie, days in 28 days in which a patient is alive and not on a ventilator) to reduce the sample size needed for clinical trials by combining “bad outcomes”—death and prolonged ventilation. Limitations with these composite variables relate to potential opposite effects of the intervention (eg, results in improved mortality but longer time on a ventilator); imprecise or variable definitions (eg, how to handle noninvasive ventilation), which limit generalizability; and potential limited importance to the patient.

It is also unclear if these surrogate short-term outcomes truly measure patient morbidity. It is critical that surrogate outcome measures relate in a meaningful way to patient-centered outcomes. Does longer length of time on a ventilator translate into more functional disability for patients after they leave the hospital, or several years later? Short- and longer-term measures of morbidity are increasingly being used for clinical research studies (ie, functional status at hospital discharge, neurodevelopmental outcome at 12 or 18 months), which are clearly relevant and important. However, these studies are challenging as well: There is variability in the instruments used to assess long-term outcomes along the developmental spectrum, and the studies are expensive and difficult to conduct. Most are labor intensive, and patients may be lost to follow-up. On the other hand, there exists at least the opportunity to follow patients for decades after the initial event, to truly understand the lifetime of consequences that may result from critical illness or injury.

Limited Translation From Bench to Bedside

The complexities of critical illness pose big challenges to bench models for disease progression and therapy. Despite many excellent animal models for sepsis, therapeutic strategies that have targeted specific factors in the causal pathway for sepsis have nearly all been negative. When moving to pediatric sepsis, the additional factors related to the variable immune response as a function of maturation and development add further complexity to this picture. Although there have been several successes, the difficulty in creating animal or in vitro models that account for the developmental components of a disease process has limited relevant bench research.[69] For example, while there are a multitude of pediatric researchers concentrating on animal models related to developmental aspects of the lung, there are still little data that characterize how the inflammation seen in ARDS may differ on the basis of age or development.[70] Although most theorize that there is indeed a relationship between the pathophysiology of ARDS and lung growth and development, sparse bench data support this, perhaps related to complexities in creating appropriate models. Certainly there are success stories of pediatric critical care investigators who have translated findings from bench to bedside, but most major successes have occurred in fields outside of critical care.

Perceptions of Cherry-Picking and Haphazard Borrowing From Adults

For a variety of reasons, pediatric critical care often looks to adult critical care for day-to-day patient management and research. Many of the large pediatric clinical trials have first been conducted in adults.[1,4,61] Such studies are much more readily conducted in adult ICUs because of the larger volume of patients and researchers in adult critical care compared with pediatrics, but some view pediatric critical care research as less novel in identifying new questions. Of course, there can be extraordinary innovation in pediatric critical care research, such as the initial approach to surgical palliation for single-ventricle physiology or use of veno-venous in preference to veno-arterial extracorporeal life support. Translation of adult research protocols to the pediatric setting in and of itself requires careful consideration and innovation. Many examples of research interventions that have been successful in adults exist, but they do not have the same results in children.[4,9] The differing results may be the consequence of many factors such as disease severity, physiologic development, and comorbidities. Nevertheless, there are still other studies and principles that are almost universally embraced, without pediatric-specific evidence. Even with evidence, there may be differences in pediatrics.[71,72] Finally, and conversely, there are a host of therapies and management strategies that pediatric practitioners use routinely, despite adult evidence indicating that they may not be beneficial.[48,49,73,74] These actually provide opportunity for investigation.

Complex Interplay Between Disease Progression and Therapy

One of the unique challenges to critical care research is that nearly all disease processes have been altered by therapy by the time the patient reaches the ICU. One can truly understand the potential therapeutic benefits for antibiotics for otitis media because patients can be randomized to receive antibiotics or no antibiotics. We could

then understand the natural history of the disease and what would be expected if the patient was not treated. However, the inherent nature of most acute care physicians, especially intensivists operating in the setting of immediately threatening instability, is to intervene. When patients arrive with severe asthma, within hours they may receive steroids, inhaled and possibly IV beta agonists, magnesium, anticholinergics, Heliox, aminophylline, and bilevel positive pressure ventilation. Each of these interventions has an expected time to therapeutic effect, but it is rare to wait for the intervention to take full effect before adding the next therapy. The result is lack of clarity regarding what made the patient better.

Determining the impact of specific elements of treatment is further complicated because patients appear in the ICU at various points in the disease process, having received different treatments before arrival. A child who is 5 days into a case of ARDS who has an oxygenation index of 40 may be very different from a child who shows up in the emergency department with 6 hours of the onset of symptoms and proceeds to require intubation for ARDS related to pneumonia, with the same oxygenation index of 40. The first child has been exposed for 5 days to medical therapies intended to support her severe lung disease, while the second has received limited medical intervention. They are also, of course, in very different stages of the disease process, and therapies may need to be tailored to these differences. Early administration of some therapies is crucial to successful outcome (ie, antibiotics at the first sign of sepsis), while others may be instituted for persistent disease that has been unresponsive to other therapies (ie, high-frequency oscillatory ventilation). Research studies must address or control for patient characteristics that include timing and evolution of disease, as well as previous therapies through careful consideration of the expected physiology, inclusion and exclusion criteria, etc.

Relative Value of Research as a Specialty

In general, pediatric training programs place some value on research, as scholarly work is required by the American Board of Pediatrics and for academic promotion. Although all pediatric critical care fellows are trained in some aspect of research, most will not go on to generate new knowledge in their career. In pediatric critical care nursing, formal research training occurs at the doctorate (ie, Ph.D.) level. This is not unique to pediatric critical care, yet motivated and well-trained researchers are essential for the growth and advancement of any field. Financial pressure on clinical departments may increase demands on even some of the most qualified and experienced junior investigators to assume very large clinical workloads. Factors contributing to these demands include the reimbursement mix of individual hospitals, 24/7 coverage models, the value of research to an institution or department, the rates of extramural or intramural funding, extent of philanthropic support, administrative or service duties, and need for work-life balance. Increasingly, research is marginalized by these other factors, and investigators initially motivated and excited to do research become discouraged or lack adequate support or recourses to be successful.

Variable Management Strategies

Among common themes to management of critically ill patients, there is significant interinstitution and intrainstitution variability in management strategies for a variety

of disease states and even for routine management of sedation, fluid status, antibiotics, ventilator support, vasoactive-inotropic support, and so on. There are few systematic, agreed-upon protocols that are used within institutions and even fewer across institutions. In many ways, practice variability has some advantages, as therapies can be best tailored to the individual patient. In addition, if we can analyze the practice variability with advanced mathematics and statistics approaches, it may be possible to discover best practices. This approach is the focus of the ongoing ADAPT trial (http://www.adapttrial.org/) that is attempting to identify best practices for pediatric traumatic brain injury. However, for most clinical research studies, this practice variability introduces bias and the variability may dilute the treatment effect of a proposed intervention. For example, in considering the relationship between a variable of interest and ventilator-free days, it is readily apparent that the results of the intervention might be confounded by variable management of sedation or extubation practices. This has been well illustrated in previous pediatric critical care studies.[75] For example, a PALISI investigation found no difference in length of ventilation among three modes of ventilator weaning, but the biggest confounder and determinant of length of ventilation was the level of sedation.[75] Without specifically controlling for sedation, which was variable across and within institutions, it was difficult to draw firm conclusions about whether weaning strategy affects length of ventilation.

ICU Stay Is Not the Patient's or Family's Entire Experience

Critical care research is increasingly complicated by preexisting comorbidities and experiences, as well as long-term effects of ICU-based therapies. As researchers increasingly consider patient-centered outcomes beyond mortality (eg, functional status, cognitive impairment) (see also Chapter 8), it is even more important to consider the status of the patient before ICU admission in evaluating the effect of ICU interventions. There are limited tools available to control for the preexisting state of the patient, and many of them are subject to recall bias of caregivers who are often asked to fill out developmental questionnaires at times of high stress and anxiety. Limited ability to evaluate pre-ICU function complicates assessment of the attributable change in functional status as a consequence of an ICU intervention. Moreover, some scales cannot differentiate significant changes in functional impairment for subsets of children with severe preexisting disability,[2] resulting in potential exclusion of a large subset of patients from research studies. Furthermore, findings of decrements in long-term function after ICU admission may not be attributable to ICU specific therapies, as there are a multitude of additional complex confounders related to new chronic illness or disability, family dynamics and changes, and psychosocial or posttraumatic stress from critical illness or the events leading to the ICU stay. To that end, several outcome meaures are uniquely important to pediatric critical care, particularly related to the effects of the child's critical illness on the family or caregiver, the child's neurodevelopment, school function, learning, attention, behavior, and functional status.

Opportunities for Pediatric Critical Care Research

Many of the aforementioned strengths and weaknesses can be turned into opportunities for the future. Some of the biggest opportunities lie in the realms of big data and informatics; precision science approaches; novel medical devices designed with children in mind, which can be translated back to adults; secondary use of existing data; and adaptive methods to overcome some of the biggest hurdles in pediatric critical care clinical trials.

Informatics and Big Data

The ICU is a natural environment for big data applications and informatics research. The amount of ICU patient data stored in the electronic health records, physiologic monitors, custom databases, and laboratory feeds is massive (see also Chapter 12). Much of these data are available for secondary analysis and research and are enticing for computer scientists and machine learning researchers looking for clinical partners who can help interpret findings. There have been numerous examples of successful collaborations among intensivists, engineers, and computer scientists that have not only resulted in interesting publications but also informatics-based solutions to critical care problems.[59,76-81] Such collaborations have potential to translate into smarter solutions for patient monitoring, predictive analytics to prevent complications or suggest therapies that may benefit an individual patient, and precision science approaches based simply on existing data. The ICU is a natural environment for these endeavors because outcomes can be objective and measured quickly, with an abundance of supporting data. The analytic techniques may be complicated given that most ICU data are inconsistently sampled. Repeated time series analysis, which mandates specific mathematic techniques, may be useful in this setting.[78] Computer scientists want to tackle these problems in concert with clinical partners.

Precision Science (e.g., Genomics, Proteomics)

Critical illness provides a fascinating framework to understand the complex interplay between the development or severity of critical illness and genetic- or biomarker-based risk stratification. Numerous examples of genes have been implicated in susceptibility to certain types of critical illness, and more and more data are emerging about using serum- or plasma-based biomarkers to risk stratify adult and pediatric patients with some of the most common and lethal critical illnesses such as sepsis and ARDS.[5,82-92] Although these analyses were initially limited to only the most sophisticated research laboratories, point-of-care testing is now becoming a reality. Access to this information may be helpful in therapy decisions on the basis of a priori risk from genetic factors or biomarker expression. These may form the basis of new, smarter clinical trials targeting therapies designed to benefit specific subgroups of patients, rather than treating all patients perceived to have the same clinical syndrome (such as sepsis or ARDS) as if they comprise a homogeneous population.[5,83,93-96] This approach has revolutionized cancer therapeutic trials and has great promise for future research in critical care.

Novel Diagnostic and Therapeutic Approaches to Deal

With the Developmental Spectrum

Children cared for in ICUs present special challenges because of age, size, and developmental ability. Because they are frequently viewed as vulnerable populations, children are often excluded during the creation of new medical devices, drugs, or diagnostics. When these drugs or diagnostics are designed for adults, adapting them for children may be difficult, requiring significant reengineering and substantial cost, often resisted by device or drug manufacturers because of the marginal gain anticipated from the “small” pediatric market. However, if the innovation starts with children in mind, it is likely that a formulation of drug or medical device will be adaptable for adults, as has been done with surfactant (see earlier). This drives innovative solutions that can ultimately be translated back to older children and adults.

Existing Data Approaches

As mentioned in the strength section, there is an increasing amount of existing data related to pediatric critical care readily available for research, which can be used to generate or test hypotheses. Although many of these data sources used individually have limitations, newer analytic techniques enable linking discrete datasets, even without patient identifiers. This significantly increases the number and type of data elements available to control for potential confounding variables and answer a question, allowing for more robust conclusions. There are increasing numbers of pediatric critical care investigators with specific training or interest in techniques to analyze existing data, and it is an exciting new area for young investigators with few barriers to entry. Training or knowledge of appropriate analytic techniques is essential,[51] but this research is generally inexpensive, can be accomplished quickly, and requires limited equipment.

Smart Clinical Trial Design

Many therapies have been shown to be beneficial in adults but lack evidence of efficacy in children. Newer statistical approaches may facilitate designing more feasible clinical trials in children, particularly when adult data are supportive of a therapy. Pediatric critical care researchers often struggle to design trials that are feasible and have important clinical outcomes, given the overall better outcome of critically ill children compared with critically ill adults. Approaches such as Bayesian clinical trials afford the opportunity to adapt the trial to information that accrues during the trial.[97] This can allow the design of the trial to be modified, change accrual targets, drop or add treatment arms, or focus the recruitment on subpopulations of patients who are responding to the treatment. Bayesian trials also allow for using historical information (such as adult data) to synthesize results of relevant trials. These approaches seem well suited for pediatric critical care research, in which researchers are often burdened with relatively rare diseases and a heterogeneous patient population and treatment effect.[98]

Threats to Pediatric Critical Care Research

Unfortunately, there are many challenges to the continued success of pediatric critical care researchers. Some have been outlined in the weaknesses section, but there are additional major threats. These challenges include limited extramural funding, the academic focus of discovery, confusion about the role of our subspecialty, the segmentation of the pediatric critical care market away from research intensive institutions, consent rates for pediatric studies, and the perception of a “small pediatric market,” as discussed later.

Extramural Funding

Federal funding for research has decreased in real terms since 1998, making it challenging for all but the most experienced of investigators to develop sustainable programs of funded research. The home for pediatric critical care research in the NIH is the Eunice Kennedy Shriver National Institute of Child Health and Development (NICHD), which has a specific Pediatric Trauma and Critical Care branch but a limited budget compared with other institutes, making it difficult for NICHD to fund many studies that have the potential to change clinical practice. Pediatric critical care investigators often seek funding from other agencies within the NIH (eg, NHLBI, NINDS), where there may be limited experience with or knowledge about pediatric diseases.[1,2] Moreover, the substantially smaller burden of pediatric critical illness compared with either acute or chronic disease in adults makes it more challenging to fund large-scale studies in pediatric critical care. While there are opportunities through private philanthropy, foundations, and intramural funding, the missions of each of these funding sources may limit the focus of investigator-initiated research and discovery. Limited funding makes it difficult to obtain preliminary data resulting in few pediatric first-in-human studies. Funding agencies are often unwilling to take risks on investigators or ideas with high potential for reward if the risks of failure have not been minimized. This reality can crush innovation.

Academic Approach to Science

The classic paradigm of a single-academic physician who excels as clinician, investigator, and educator (the “three-legged-stool”) is no longer realistic for the vast majority of intensivists. Instead, it is increasingly common for critical care clinicians (and other subspecialists) to develop strength or expertise in one or two domains. It is particularly difficult to be successful as an investigator without substantial protected time for research. Protecting the time of junior investigators until they secure extramural funding can be an expensive proposition and may not be possible without significant ongoing departmental commitment or intramural funds. The difficult funding environment exacerbates this problem: Investigators may become discouraged when excellent proposals, which would have previously been funded, are not successful. More and more, departments provide protected time only to investigators with special training or established track records of funding. Increasingly, the importance of obtaining funding to support one's research has been reallocated solely to those holding research-tract appointments.

Confusion About the Role of Our Specialty

Ultimately, pediatric critical care is a supportive specialty and a service line for most hospitals. While philanthropists often visit the critical care environment, patients infrequently come to a particular hospital because of the ICU services. They may come to see a particular surgeon or other pediatric subspecialist who is an expert for their disease condition. When a patient develops ARDS, parents rarely request transfer to one ICU over another because the ICU has an ARDS expert. More commonly, transfer occurs only when the complexity of care becomes too great for a smaller ICU or specific technologic support is only available at another center. Hence, from the viewpoint of many administrators, investing resources in the ICU (especially for research) may be harder to justify as the ICU itself is not bringing in patients and generating revenue. Moreover, there is often little understanding, particularly with the public or potential philanthropists, about what types of patients are treated in PICUs. While the public may have experience or understanding of neonatal ICUs with premature babies or adult ICUs because of family members who have had heart attacks or strokes, most people never have any interaction with the PICU. This makes fundraising for research in pediatric critical care even more challenging because the PICU is an unknown entity for so many. Making a clear case to administrators and the general public about the central role of critical care in modern health care, enabling effective management of children with disorders as varied as respiratory failure from asthma or common viruses, cancer, congenital heart disease, transplantation, and trauma, is essential if critical care is to receive its share of resources needed to improve outcomes.

Segmentation of the Pediatric Critical Care Market Away From Research Institutions

An increasing number of smaller hospitals are developing pediatric critical care services to retain patients within their hospital system and attract specialists who are likely to generate revenue for the hospital. Depending on the market or city, there may be dozens of hospitals that have PICUs, with selective referral patterns based on perceived acuity of the patient, insurance type or status, or family preference. The resulting dilution or modification of the patient population at academic research institutions limits the opportunity to conduct research, particularly on the most common disorders, and limits the generalizability of research findings. For example, if 90% of patients enrolled in a research study about a new therapy for pediatric sepsis have significant preexisting comorbidities including cancer or immunosuppression, the results may not be applicable to a child who is previously healthy and develops sepsis. Increasingly, there is a discrepancy between the types of patients seen in academic research centers and other community-based ICUs. If these community-based ICUs do not participate in research studies (because they have no infrastructure for research), researchers may not be effectively testing generalizable research hypotheses.

Consent Practices for Clinical Trials in Children

In general, consent rates for pediatric critical care research trials are lower than for adults. Probably more importantly, because children are considered vulnerable populations, the risk-benefit profiles are often more heavily scrutinized by both

institutional review boards and parents. It is therefore often difficult to get consent for pediatric critical care studies when there is limited or no potential benefit for the child. This changes the design of many research studies and may affect the ability to definitively answer the research question. Issues related to patient assent are also complicated. Ascertaining whether the child is of appropriate developmental ability to assent may be subjective. Obtaining assent or consent from many of the children who are of appropriate age or developmental status may not be possible because they are critically ill, often sedated, and intubated. Moreover, practices related to assent are highly variable across institutions and institutional review boards.[23,60,99]

With the limited number of pediatric institutions engaging in clinical research, there is frequently overlap of investigations within a single institution, with multiple research studies competing for the same patients. Parents and families can develop “study fatigue” and become resentful of requests for consent perceived to be excessive. Investigators must be aware of all the other studies the families may be approached to participate in and whether the studies can allow for coenrollment. If not, prioritization of the studies becomes necessary, which ultimately may result in inadequate recruitment and loss of funding for some otherwise meritorious investigations.

Perception of Pediatrics as a Small Market

Maintaining solvency in the medical technology and pharmaceutical industry is challenging. While there has been incredible growth in the number of medical devices and drugs on the market in recent years, there is also intense competition. Smaller companies are frequently bought by large multinational organizations only after their products have become profitable and achieved adequate market share. For the most part, pediatric indications and devices do not drive these profits. As a result, a large company is unlikely to make a significant investment in a pediatric-specific product. Smaller companies may be more willing but still may be reluctant if there is no clear adult market potential, as they will not be able to sell their business to a larger company. While there have been some federally funded initiatives to foster research and development into pediatric specific devices and drugs, academic partnership with industry for the development of a pediatric specific device or drug is still extremely difficult.

Conclusions

Despite multiple threats, there are reasons to be optimistic about the future of pediatric critical care research. Research paradigms are changing, and increasingly there are new applications, data sources, methods and techniques that will revolutionize the way researchers approach scientific problems. Researchers in pediatric critical care have taken the lead in how best to interact and involve families in clinical care and complex decision making. Using adaptive clinical trial design that may make working with smaller populations more successful is becoming more common. Most pediatric intensivists are eager to participate in multi-institutional trials and most exhibit increasing sophistication regarding the design and value of research. More intensivists and Ph.D.-prepared nurse scientists with specialized research training (T-32, K-08, K-23, and K-12 programs) are required to justify

protected time. In the past, pediatric intensivists were nearly entirely devoted to keeping the child alive in the moment, but over the past 10 to 15 years, there has been significant development of clinician-scientists in pediatric critical care focused on answering important questions about mechanisms and treatment of disease. As a community of pediatric critical care practitioners, we will need to continue to embrace innovation and stimulate the newer generation of clinician scientists to not be afraid of breaking the traditional mold of the academic-scientist to discover new knowledge regarding the care of critically ill children.

CHAPTER 8

Proving the Point

Evidence-Based Medicine in Pediatric Critical Care

R. Scott Watson, Mary E. Hartman, Derek C. Angus

"Not all clinicians need to appraise evidence from scratch, but all need some skills."[1]

PEARLS

- Physicians have an ethical and clinical obligation to use the best available evidence whenever applicable.
- The evidence base for critical care is growing rapidly.
- Practicing evidence-based medicine is straightforward, and keeping up with relevant evidence is becoming easier and less time consuming.
- PubMed includes research methodology filters (found under the "Clinical Queries" heading) that enhance the efficiency of searching the literature.
- Multiple evidence-based medicine–related resources can be found on the Internet.

Evidence-based medicine (EBM) is simply the integration of the best available evidence with individual clinical expertise and patient preferences.[1,2] One could easily make the incorrect assumption that its practice is, and always has been, ubiquitous. However, proven interventions are often misapplied, and striking variations in clinical practice (not attributable to patient differences) occur even when high-quality evidence is available.[3-8] Practicing EBM in critical care in general and pediatric critical care in particular poses unique challenges. Decisions that can have profound implications for a child and his or her family must be made quickly and, until recently, with little good external evidence. However, pediatric critical care and EBM both have matured to the point that EBM is an indispensable and realistic component of optimal practice.

Despite decades of international support and growth, the practice of EBM

continues to be hindered by misconceptions. It is not “cookbook medicine” that suppresses the individual freedom of practitioners.[9] It is not a cost-cutting tool. Treatments found to be effective may be more expensive than the previous standard of care. It is also realistic to think that physicians in the “real world” can practice it. Advances in literature search engines and the increasing availability of EBM resources make it accessible and applicable for busy clinicians.

This chapter provides an overview of the steps in practicing EBM, including definitions of selected terms used in EBM (Appendix A, available online at http://www.expertconsult.com). Critical care is in the midst of a groundswell of outstanding clinical research that is improving the outcome of critically ill patients. Our goal is to demystify the process of EBM so that pediatric intensivists can incorporate it as a fundamental element in their practice.

Evidence-Based Medicine Process

The steps in the EBM process are straightforward: (1) define the problem, (2) search for relevant evidence, (3) evaluate the evidence, and (4) apply the evidence.

1. **Define the problem.**

The practice of EBM always begins and ends with a patient. Defining the problem in EBM terms requires the provider to frame the problem in a way that will ultimately inform care.[10] The key components to a focused EBM question include:

a. The patient (or population) with a specific disease, demographic characteristics, or risk factors

b. The intervention or exposure in need of greater understanding (eg, a medication, test, disease, environmental exposure)

c. The comparison or main alternative to whatever one wishes to do (there may not always be one)

d. The outcomes of greatest interest

Ultimately, clinical EBM questions will fall into one of four categories: (1) diagnosis, (2) therapy, (3) prognosis, or (4) etiology or harm. The category of clinical question, in turn, dictates the kinds of studies that are most relevant. For example, questions about therapy are usually best answered with a randomized controlled trial (RCT) or systematic review. On the other hand, to determine the prevalence of a disease or risk factors for its development, observational studies are necessary (see “Types of Studies” later).

2. **Search for relevant evidence.**

Medical subject headings (MeSH) are descriptive terms assigned to each bibliographic reference in Medline by the National Library of Medicine. There are 27,149 descriptors in the 2014 MeSH, organized into a hierarchical structure (http://www.nlm.nih.gov/pubs/factsheets/mesh.html). At the top level are broad headings such as “Diseases” or “Organisms.” More specific headings are found at more narrow levels of the 12-level hierarchy, such as “Sepsis” and *“Neisseria meningitidis.”*

There are also more than 218,000 cross-reference entry terms that assist users in finding the most appropriate MeSH (eg, "MODS, see Multiple Organ Failure"). An online, searchable list of the entire MeSH vocabulary and suggestions for key words is available at the National Library of Medicine (http://www.nlm.nih.gov/mesh/meshhome.html). Online search engines have incorporated many of these terms into easy-to-use research methodology filters for clinicians. PubMed, for example, allows searchers to select filters for studies of etiology, diagnosis, therapy, and prognosis. Similar filters can be found in Ovid Technologies' search engine, in addition to filters on clinical prediction guides, qualitative studies, costs, and economics. In both, the choices are presented under the "Clinical Queries" heading. Highly sensitive searches produce comprehensive retrievals (particularly useful for subjects in which little work has been done), highly specific searches retrieve only the most rigorous studies and little nonrelevant material (for subjects in which much work has been published), and optimized searches maximize the tradeoff between sensitivity and specificity.[11-13]

In addition to Medline, other specialized databases and Internet-based resources are available that can yield relevant results quickly. Table 8.1 lists a sample of these resources. One of the best known is the Cochrane Library, which contains a large collection of peer-reviewed systematic reviews of health care interventions.[14] It is thoroughly indexed and easily searched. In addition, the PedsCCM Evidence-Based Journal Club posts critical reviews of studies related to pediatric critical care.

3. **Evaluate the evidence.**

Study Types

Interventional Studies

Interventional studies are clinical experiments, the strongest of which is the RCT, the gold standard in the assessment of the efficacy of an intervention.[15,16] Randomization minimizes the risk of an unequal distribution of known and unknown factors (confounders) that may influence patient outcome. The presence of a control group helps distinguish changes in outcome that result from the therapy in question from changes that otherwise would have occurred. Because of their high cost, RCTs are usually designed to maximize the likelihood of finding a positive effect. Therefore they tend to be efficacy studies, with highly selected patient populations treated by experienced providers. The effectiveness of a therapy as used in general practice (rather than in the specific, carefully controlled setting of an RCT) often requires additional study, usually through subsequent observational studies.[17] See Box 8.1 for

factors to consider in appraising the quality and applicability of interventional studies.

Box 8.1

Critical Appraisal of a Study of Therapy

Are the Results of the Study Valid?

1. Were patients effectively randomized?
2. Were all the patients accounted for?
3. Was follow-up complete?
4. Were patients analyzed according to how they were randomized (ie, intention to treat)?
5. Were all people involved in the study blinded?
6. Were the groups similar at the start?
7. Were the groups treated equally apart from the experimental intervention?

Are the Results Clinically Useful?

- How large was the treatment effect?
- How precise was the estimate of the treatment effect?
- Are the patients similar to the "norm"?
- Were all clinically important outcomes considered?
- Was a cost-to-benefit analysis performed?

Adapted from Sackett DL, Straus SE, Richardson WS, et al. *Evidence-Based Medicine: How to Practice and Teach EBM.* 2nd ed. London: Harcourt; 2000.

Observational Studies

The principal alternative to experimental studies involves observation. Observational studies are powerful tools for addressing many questions that RCTs cannot and for generating hypotheses that can be tested in interventional trials. They can elucidate epidemiologic characteristics and prognosis of diseases or effects of organizational characteristics on outcome. They can provide information on a treatment's effectiveness (vs. efficacy) and determine cost-effectiveness. They have become increasingly sophisticated, but, as with all study types, they have limitations. Confounding may be difficult to control. Even if known confounders are well controlled, unknown or unmeasured confounders may influence results. Selection of an appropriate control group is crucial but can be difficult. Different kinds of

observational studies address different types of questions.

In **case-control studies,** researchers compare subjects with a particular outcome (cases) with subjects who do not have the outcome (controls). Ideally, the case and control subjects are identical except for (1) the outcome of interest and (2) the risk factor or exposure that leads to the outcome of interest. With such a study, risk factors or exposures that are responsible for the outcome (eg, smoking as a risk factor for lung cancer) can be identified. Of course, finding groups of patients that are so nearly identical is impossible. However, well-done case-control studies that include rigorously selected cases and controls can be extremely informative. They often are the only feasible study method for uncommon outcomes or when the lag time between an exposure and outcome is long.

Cross-sectional studies provide a snapshot of a population at one point in time. They can identify the prevalence of a condition, such as of sepsis among patients in an ICU. They are relatively inexpensive and can be conducted in a short time. Cross-sectional studies usually establish only association, not causality.

In **cohort studies,** researchers follow a group of subjects through time, recording exposures and outcomes. Cohort studies have a number of strengths, including the ability to establish the timing and sequence of events and provide population-based results. The best cohort studies measure exposures and outcomes in a blinded, objective manner; have long and complete follow-up; and identify known confounders.

Case reports may be the only available information in support of a therapeutic strategy, especially for extremely rare or fatal conditions. The difficulty generalizing from case reports makes them among the weakest forms of clinical evidence.

Research Summaries

Research summaries that provide a standardized, thorough critique of studies are particularly valuable for busy clinicians. Single studies can be presented in a standardized format called a *critically appraised topic*.[18] Multiple studies of a single topic can be summarized in several different ways. **Narrative reviews** include traditional review articles and textbooks. A knowledgeable author reviews the literature, formulates an opinion, and disseminates this opinion along with references to support it. Narrative reviews can provide a detailed qualitative discussion that is easy to comprehend, is well organized, and synthesizes tremendous amounts of information. Unfortunately, the literature is rarely searched and evaluated in an organized, reproducible manner. Inherent lags in publishing times can make them an unreliable source of current information. For example, in 1988, pooled data from nearly 9000 patients with acute myocardial infarction in 15 studies on the use of prophylactic lidocaine in patients showed that the practice was useless at best. Nonetheless, in 1990, narrative review articles and textbooks still contained more recommendations for its use than against it.[19]

A **systematic review** combines the results of multiple studies through the systematic search, assembly, and appraisal of primary research. Search criteria are predefined, including the inclusion and exclusion criteria for individual studies. The methods section provides search terms and key words to establish reproducibility. They can provide an excellent summary of the literature up to the date of the review. The main disadvantage is that they are only as good as the studies they include.

However, even when the studies are weak, systematic reviews can be an important means by which to identify gaps in evidence and thus outline a research agenda.

In a **meta-analysis,** data are combined from multiple studies to yield a quantitative summary. If the combined studies use similar methodology and are of high quality, meta-analyses can increase the power to find an effect. However, difficulties in interpretation of summary statistics arise when meta-analyses combine studies that vary in quality, population, or intervention.

Levels of Evidence

One of the most widely used taxonomies for classifying evidence and clinical recommendations comes from the Oxford Centre for Evidence-Based Medicine (Appendix 8B, available online at http://www.expertconsult.com). Each study can be assigned a level of evidence based on its design and quality. For a given topic, the quality of the entire body of evidence forms the basis for the strength (or grade) of a clinical recommendation. The best studies are level 1a evidence (systematic reviews of studies using similar methods), and the weakest studies are level 5 evidence (expert opinion). Clinical recommendations are then graded from A (consistent level 1 evidence) to D (level 5 evidence or troublingly inconsistent or inconclusive studies).

4. **Apply the evidence.**

The strongest evidence is useless unless it is effectively applied (Box 8-1). Clinicians must use their knowledge and experience to understand how the results of studies can be applied to individual patients. With evidence in hand, a clinician practicing EBM will place it in the context of the specific clinical circumstances and the patient's (or guardian's) preferences.[20] Patient characteristics or preferences may be sufficiently uncommon to render even good evidence inapplicable.

EBM can be implemented on a larger scale through clinical practice guidelines and clinical pathways, which can disseminate and promote best practice at institutional, regional, or national levels. They are especially useful for common illnesses and procedures, and they allow implementation of EBM even when individual physicians are unable to incorporate evidence by themselves because of a lack of either time or expertise. The most compelling guidelines contain a summary of the evidence both for and against the guideline and how to apply the recommendations to specific clinical situations.[18]

Challenges to Evidence-Based Medicine

Until recently, a paucity of strong evidence existed to support particular care paradigms in the critically ill, with even less evidence related to critically ill children. A basic tenet of EBM is that a lack of evidence that an intervention is effective is *not* proof that an intervention is ineffective (ie, "Absence of evidence is not evidence of absence"). This issue is particularly relevant to pediatric critical care, in which numerous therapies are used without proven efficacy, and the evidence base for many other therapies is from studies of adults. Whether unproven therapies should be used depends on (1) whether proven alternatives are available, (2) the likelihood

and magnitude of potential harm from the therapy, (3) the natural history of the disease or condition being treated, (4) in the case of prophylaxis, the risk of developing disease, and (5) the cost of treatment (as well as the cost of not treating the patient).

Conclusion

The practice of critical care is changing constantly, but studies documenting remarkable practice variation suggest that the change is much too inconsistent. Intensivists tend to be resourceful, creative, efficient, experts in pathophysiology and comfortable with applying clinical skills to desperate circumstances amidst a paucity of evidence. Although critical care physicians often have both the predilection and facility for making important decisions quickly and independently, that same temperament may impede the acquisition and application of a growing body of evidence related to critical illness and critical care.

All physicians have an ethical responsibility to apply EBM. Meticulously designed and executed clinical research is expensive and difficult to perform. Society expends scarce resources on it. Subjects in clinical trials face significant personal risks in hopes of a better outcome and for the advancement of knowledge. Our responsibility extends beyond individual patients, for whom the benefits of using the best available treatment are usually clear. We owe it to subjects of prior trials, researchers who carried out the trials, and the society that supported them to use and build on the knowledge gained. The unique vulnerability of critically ill patients, with their significant risk of death or long-term morbidity, creates perhaps an even stronger ethical imperative for intensivists to use evidence whenever it is available. When evidence is inadequate, we are left to do our best with our clinical expertise for our current patient and to generate the evidence needed for future patients.

APPENDIX 8A

Selected Evidence-Based Medicine Definitions and Equations

Two-by-Two Table

		DISEASE OR OUTCOME	
		Present	**Absent**
Test or exposure	Positive	a	b
	Negative	c	d

Absolute Risk Reduction (ARR): The difference in event rates in treated patients compared with control patients. Note that the order is reversed compared with the attributable risk (see definition below).

$$ARR = [c/(c+d)] - [a/(a+b)]$$

Attributable Risk (AR): The effect of an exposure on the risk of disease in those exposed compared with those unexposed.

$$AR = (\text{Frequency in exposed group}) - (\text{Frequency in unexposed group})$$
$$= [a/(a+b)] - [c/(c+d)]$$

Confidence Interval (CI): The range of values likely to include the true value for the entire population. The standard is 95%, in which 95% of such intervals will contain the true population mean.

Intention-to-Treat Analysis: Data are analyzed according to the groups to which subjects were assigned, regardless of what treatment subjects actually received ("analyzed as randomized").

Negative Predictive Value: The proportion of people with a negative test who are free of disease: d/(c + d).

Number Needed to Treat (NNT): The number of patients needed to treat to achieve one outcome. It is the inverse of the ARR (1/ARR).

$$NNT = 1/[c/(c+d) - a/(a+b)]$$

Odds: The ratio of events to nonevents (ie, chances of something happening divided by chances against something happening). This is not the same as risk (which has a different denominator; see definition below). The odds of getting "heads" when flipping a coin are 1 : 1 (one to one).

Odds Ratio (OR): The odds of an event in a treated patient versus the odds in a control patient. In case-control studies, relative risk (RR) cannot be calculated because subjects are selected on the basis of outcome, not exposure. For rare outcomes (eg, <10% of the population), RR can be estimated by OR.

$$OR = \frac{a/c}{b/d} = \frac{ad}{bc}$$

Positive Predictive Value (PPV): The proportion of people with a positive test who have disease: a/(a + b).

Sensitivity: The proportion of people with disease who have a positive test: a/(a + c).

Specificity: The proportion of people free of disease who have a negative test: d/(b + d).

Relative Risk (RR): The risk of development of disease in the exposed group relative to those who were not exposed (also called *risk ratio*).

$$RR = \frac{\text{Prevalence in exposed group}}{\text{Prevalence in unexposed group}} \frac{a/(a+b)}{c/(c+d)}$$

Relative Risk Reduction (RRR): Percent reduction in events in treated versus untreated groups.

$$RRR = (1 - [a/(a+b)]/[c/(c+d)]) \times 100\%$$

Risk (probability): The ratio of events to all possible events (ie, the chances of something happening divided by the total number of chances). The risk (probability) of getting "heads" when flipping a coin is 0.5, or 50%.

Type I Error (α): The chance that a difference between treated and control groups studied is found when, in reality, there is no difference.

Type II Error (β): The chance that no difference between treated and control groups studied is found when, in reality, there is a difference.

Power (1–β): Statistical power is the ability of an experiment to find a significant difference between groups when a difference exists.

APPENDIX 8B

Levels of Evidence for Study of Therapy or Prevention From the Oxford Centre for Evidence-Based Medicine

Level[a]		Description
1	1a	Systematic review (with homogeneity[b]) of RCTs
	1b	Individual RCT (with narrow confidence interval)
	1c	All or none[c]
2	2a	Systematic review (with homogeneity[b]) of cohort studies
	2b	Individual cohort study or low-quality RCT (eg, <80% follow-up)
	2c	Ecologic studies
3	3a	Systematic review (with homogeneity) of case-control studies
	3b	Individual case-control study
4		Case series (and poor-quality cohort and case-control studies)
5		Expert opinion without explicit critical appraisal or based on physiology or bench research
Grades of Recommendation		
A Consistent level 1 studies B Consistent level 2 or 3 studies *or* extrapolations from level 1 studies C Level 4 studies *or* extrapolations from level 2 or 3 studies D Level 5 evidence *or* troublingly inconsistent or inconclusive studies of any level		

[a]A minus-sign "−" can be added to denote that evidence fails to provide a conclusive answer because of either a single result with a wide confidence interval or a systematic review with troublesome (or statistically significant) heterogeneity.

[b]Homogeneity denotes a systematic review that is free of concerning variations (heterogeneity) in the directions and degrees of results between individual studies.

[c]Met when all patients died before the treatment became available, but some now survive with it OR when some patients died before the treatment became available, but none now die with it.

RCT, randomized controlled trials.

CHAPTER 9

Prediction Tools for Short-Term Outcomes Following Critical Illness in Children

Michael C. Spaeder, Murray M. Pollack

PEARLS

- Physiologic instability is a key factor in the prediction of short-term outcomes in critically ill patients.
- Prediction tools are central to controlling for severity of illness in studies and unit-based quality assessments for both internal and external benchmarking.
- Regression analysis is typically the central technique for the construction of outcomes prediction tools.
- Assessment of the validity of prediction tools centers on two statistical measures: discrimination and calibration.
- Although mortality has historically been the predicted outcome, prediction tools for morbidity have recently been developed.

Introduction

Current efforts to provide high-quality, error-free care require the evaluation of complex systems and the assessment of quality of care. Outcomes research is an important aspect of both requirements. Scoring systems add objectivity to these assessments, especially in critical care units. Controlling for population differences such as differences in severity of illness enables both the inclusion of different health care systems in a single investigative effort and contrasting individual health care systems in quality of care assessments. Mortality adjusted for physiologic status and other case mix factors has been the core methodology of adult, pediatric, and neonatal intensive care assessments for decades. Scoring systems are basic to controlling for severity of illness in studies and unit-based quality assessments for both internal and external benchmarking.

However, mortality rates in most pediatric intensive care units (PICUs) have

decreased since these methods were developed. Medical therapies are increasingly focused on reducing morbidity in survivors. Unfortunately, quantitative outcome assessment methods continue to focus on the dichotomous outcome of survival and death. Recently, there has been a new appreciation of the importance of patient outcomes other than mortality, including discharge functional status, and better understanding of its determinants. The future will most likely see a diversity of patient outcomes of interest, methods to associate risk factors with these outcomes, and use of these risk factors for outcome prediction.

Historical Perspective

The "modern" history of intensive care unit (ICU) scoring systems started with the Clinical Classification Scoring (CCS) system, a subjective categorization of a patient's anticipated clinical needs ranging from routine inpatient care (Category 1) to frequent physician and nursing assessments and therapeutic interventions (Category 4) and the Therapeutic Intervention Scoring System (TISS).[1] Although simple, the CSS system established the basis of severity of illness as a concept related to both physiologic instability and amount and intensity of therapy. The TISS was based on the concept that as patients got sicker, they received more therapy such as mechanical ventilation or vasoactive agent infusions; thus the number and sophistication of therapies, which could be expressed numerically, served as a proxy for severity of illness. Initially, 76 therapies and monitoring techniques were graded from 1 to 4 on the basis of complexity, skill, and cost required to provide these modalities. The TISS score still exists today, although the number of therapies has been reduced and objectivity has been added to the score.[2]

The concepts of sequential or multiple organ system failures (MOSFs) were also important in the development of the concepts of severity of illness. Mortality rates increased as the number of failed organ systems increased. The MOSF syndrome was initially described in children in 1986.[3] Although there have been numerous minor adjustments to the definition of an organ system failure, they continue to be based on the initial concepts of failure defined as extreme physiologic dysfunction or use of a therapy preventing that dysfunction. Organ system failures have also been proposed as an outcome measure; since death is uncommon in PICUs, it is appealing to postulate that the number of organ failures or the temporal resolution of these organ failures could be a practical outcome.

Physiologic status is the underlying foundational concept for MOSF and the TISS score. Conceptually, severity of illness may be considered a continuous variable with extremes of outcomes (survival, death) occurring at low and high values. The threshold value determining survival or death is unknown and may vary from patient to patient. Physiologic instability has been an exceptionally productive concept expressed in multiple scoring systems in pediatric, neonatal, and adult intensive care with scores such as the Pediatric Risk of Mortality (PRISM) score, Score for Neonatal Acute Physiology (SNAP), Acute Physiology and Chronic Health Evaluation (APACHE), and many others.

Recently, the development of new morbidity during critical illness has also been related to physiologic instability, with the morbidity risk rising as the instability increases until, at higher states of instability, high morbidity risk transitions to mortality. The interest and investigations of morbidity have been hindered by the

lack of measurement methods that are reliable, relevant, and practical for large studies. The recent development of the Functional Status Scale and its use in a national study of more than 10,000 critically ill children hold promise that morbidity will be a more important and relevant outcome in critical care assessments.[4]

Methods

Conceptual Framework

When possible, the severity method should include variables fundamental to the issues being assessed. The fundamental role of pediatric critical care has been to monitor and treat physiologic instability. The development of severity measures has mirrored this role, first as descriptive categories, then as quantification of therapy designed to treat physiologic instability, and finally as physiologic instability itself as the foundational concept. As databases become larger and more data are available digitally, availability of descriptive, categorical, and diagnostic data contained in administrative and clinical databases has increased. These data can also be associated with severity of illness and are being used for quality measures such as standardized mortality ratios and measures of severity of illness in academic studies. However, variables such as diagnosis and operative status are proxy variables whose risk estimation is, at least in part, one or more steps removed from physiologic status. Therefore they are indirect measures of severity. One must be aware that data such as diagnosis are subject to “gaming” to alter an individual site's results. Methods based on primarily categorical data often do not perform well in all critical care environments.

Statistical Issues

Regression analysis is typically the central technique for the construction of outcomes prediction tools. The type of outcome variable (eg, continuous, dichotomous) is one determinant of the type of regression analysis used. Multiple linear regression analysis is most often used for models that seek to predict outcomes that are continuous variables (eg, length of stay). Logistic regression analysis is most often used for models that seek to predict outcomes that are categorical variables (eg, survival/death).

The assessment of the validity of a prediction tool centers on two statistical measures: discrimination and calibration.[5] Discrimination is the accuracy of a model in differentiating outcomes groups and is most often assessed by the area under the receiver operating characteristic (AUC) curve. An AUC = 1 represents a model with perfect accuracy while an AUC = 0.5 represents a model with no apparent accuracy. A rough guide for model discriminatory performance is as follows: AUC = 0.9–1 (excellent), 0.8–0.9 (good), 0.7–0.8 (fair), 0.6–0.7 (poor), and 0.5–0.6 (fail). Calibration refers to the ability of a model to assign the correct probability of outcome to patients over the entire range of risk prediction. In practical terms for an outcome like mortality, calibration assesses whether the model-estimated probability of mortality for patients with a particular covariate pattern agrees with the actual observed mortality rate. The most accepted method for measuring calibration is the Hosmer Lemeshow goodness-of-fit test.

An important issue in developing and evaluating severity methods is the population used to derive the method. The methods are models based on the populations used to develop them. In the following examples, the Vermont Oxford Neonatal outcome predictor was developed in a large population from inborn nurseries and has been criticized for its lack of applicability to referral centers. The Paediatric Index of Mortality (PIM) has been developed in predominantly Australian and European populations where the relationship of categorical and physiologic variables to outcome may be different from in the United States or a developing country.

Prediction Tools for Assessment of Mortality Risk

Neonatal Intensive Care Unit Prediction Methods

Three well-established prediction methods are used for the assessment of severity of illness and mortality risk in neonates: the Clinical Risk Index for Babies II (CRIB II),[6] SNAP-II,[7] and the Vermont Oxford Network risk adjustment.[8] All scores can be calculated during the first 12 hours of life.

CRIB II is the second-generation of CRIB (Cockburn 1993), which was developed on 812 neonates born less than 1500 gm or at less than 31 weeks' gestation in the United Kingdom.[9] CRIB II is a simplified version of CRIB, validated on 3027 neonates born at 32 weeks' gestation or less. It is a five-item score composed of sex, gestation, birth weight, admission temperature, and worst base excess in first 12 hours of life.

SNAP-II is the second-generation of SNAP (Richardson 1993), which was a physiology-based severity of illness score with 34 variables for babies of all birth weights from the United States and Canada.[10] SNAP-II simplified SNAP to six physiologic variables: mean blood pressure, lowest temperature, PaO_2/FiO_2 ratio, lowest serum pH, seizure activity, and urine output. In an effort to improve the predictive capabilities of SNAP-II for mortality, three additional variables were added: birth weight, small for gestation age, and Apgar (appearance, pulse, grimace, activity, and respiration) score less than 7 at 5 minutes. The resulting nine-variable score for prediction of mortality risk was named Score for Neonatal Acute Physiology with Perinatal Extension (SNAPPE-II).

The Vermont Oxford Network is a network of more than 800 institutions worldwide that maintains databases on interventions and outcomes for infants cared for at member institutions. The Vermont Oxford Network risk adjustment model includes terms for gestational age, race, sex, location of birth, multiple birth, 1-minute Apgar score, small for gestational age, major birth defect, and mode of delivery.

Revalidation efforts of these tools employing a variety of data sources have demonstrated largely similar discriminatory abilities among the tools. Using data from the Vermont Oxford Network, Zupancic et al. validated SNAPPE-II on nearly 10,000 infants with similar performance to the Vermont Oxford Network risk adjustment.[11] Within this study cohort, the addition of congenital anomalies to SNAPPE-II improved discrimination significantly. Reid et al. compared CRIB-II and

SNAPPE-II in a cohort of Australian preterm infants and found similar performance between the tools and good overall discriminatory ability.[12]

Pediatric Intensive Care Unit Prediction Tools

The prediction of mortality in the PICU has centered primarily on the use of two different acuity scoring systems, the PRISM III score[13] and the PIM3.[14]

PRISM III (Table 9.1) is a third-generation physiology-based score for quantifying physiologic status and mortality prediction. The original tool was developed on 11,165 patients from 32 different PICUs in the United States and includes 21 physiologic variables. The mortality predictions are routinely updated, the last update being completed on 19,000 patients. Among PRISM III's strengths are its flexibility to extend beyond mortality prediction to provide risk-adjusted PICU length-of-stay estimates.[15] Historically, PRISM III mortality risk assessments were made using physiologic data from the initial 12 hours of PICU care. Notably, PRISM quantifies physiologic status and uses categorical variables to facilitate accurate estimation of mortality risk.

TABLE 9.1

Pediatric Risk of Mortality (PRISM) Score III

For computation of mortality and morbidity risk, physiologic variables are measured only in the first 4 hours of pediatric intensive care unit (PICU) care and laboratory variables are measured in the time period from 2 hours before PICU admission through the first 4 hours. See references for the appropriate time periods to assess cardiovascular surgical patients younger than 3 months of age. The neurologic PRISM III consists of the mental status and pupillary reflex parameters. Only the first PICU admission is scored. Please check publications for the most up-to-date prediction algorithms.

CARDIOVASCULAR AND NEUROLOGIC VITAL SIGNS		
Systolic Blood Pressure (mm Hg)	**Score = 3**	**Score = 7**
Neonate	40-55	<40
Infant	45-65	<45
Child	55-75	<55
Adolescent	65-85	<65
Temperature	Score = 3	
	<33°C or >40°C	
Mental status	Score = 5	
	Stupor/coma or GCS <8	
Heart Rate (beats per minute)	**Score = 3**	**Score = 4**
Neonate	215-225	>225
Infant	215-225	>225
Child	185-205	>205
Adolescent	145-155	>155
Pupillary reflexes	Score = 7	Score = 11
	One fixed	Both fixed
ACID-BASE, BLOOD GASES		
Acidosis (pH or total CO_2)	**Score = 2**	**Score = 6**
pH	7.0-7.28	<7.0
CO_2	5-16.9	<5
PCO_2 (mm Hg)	Score = 1	Score = 3
	50-75	>75
Alkalosis: total CO_2 (mmol/L)	Score = 4 >34	
PaO_2 (mm Hg)	Score = 3	Score = 6
	42-49	<42
CHEMISTRY TESTS		
Glucose	Score = 2	
	>200 mg/dL or >11 mmol/L	
Potassium (mmol/L)	Score = 3	

	>6.9	
Blood urea nitrogen	Score = 3	
Neonate	>11.9 mg/dL or >4.3 mmol/L	
All other ages	>14.9 mg/dL or >4.3 mmol/L	
Creatinine	Score = 2	
Neonate	>0.85 mg/dL or >75 mmol/L	
Infant	>0.90 mg/dL or >80 mmol/L	
Child	>0.90 mg/dL or >80 mmol/L	
Adolescent	>1.30 mg/dL or >115 mmol/L	
HEMATOLOGY TESTS		
White Blood Cell Count (cells/mm^3)	**Score = 4**	
	<3000	
Platelet count (×103 cells/mm^3)	Score = 2	Score = 4 Score = 5
	100-200	50-99 <50
Prothrombin time (PR) or		
Partial thromboplastin (time) (PTT)	Score = 3	
Neonate	PT >22 or PTT >85	
All other ages	PT >22 or PTT >57	

GCS, Glasgow Coma Scale.

Recently, PRISM III underwent improvements to reduce bias and potential sources of error in more than 10,000 patients collected by the Collaborative Pediatric Critical Care Research Network (CPCCRN) of the National Institute of Child Health and Human Development.[16] Initially, PRISM used PICU outcome and subsequent PICU admissions in the same hospitalizations with additional mortality risk. But discharge decision making is an important aspect of quality of care. For example, an inappropriately discharged PICU patient with a subsequent PICU readmission during the same hospitalization was previously credited as a good outcome for the first admission, while the subsequent admission had an additional mortality risk credited to the subsequent PICU admission mortality risk. Therefore the subsequent PICU admission mortality risk was inflated even though it was associated with the premature or inappropriate discharge. The new version of PRISM III uses only the first PICU admission, and hospital outcome is predicted. Second, the PRISM observation time period has changed from the sampling period for the first 12 hours of care to a significantly shorter time period (2 hours before admission to 4 hours after admission for laboratory data and the first 4 hours of PICU care for other physiologic variables) since this better separates the PRISM score from therapies.[17] Third, admission of cardiovascular patients for “optimizing” therapy or observation before their intervention is now common in many institutions, and this necessitated a new definition of the PRISM observation period. An objective method to determine the PRISM III observation for cardiovascular patients is now available. Finally, when PRISM was initially developed, the scores for physiologic derangements for each variable were calibrated to mortality odds ratios, so the PRISM III score for each variable represented equivalent risk. Over time, new therapies have evolved and these equivalencies could have changed. This was tested and adjustments were made by partitioning PRISM into its five major subcategories. The new PRISM III algorithm partitions PRISM III into the neurologic and non-neurologic components for outcome prediction.

The PIM3 mortality prediction model was developed from 53,112 patients from 60 PICUs in Australia, New Zealand, Ireland, and the United Kingdom (Table 9.2). PIM3 requires 10 variables collected from the time of initial patient contact to 1 hour after arrival in the PICU. In contrast with PRISM III, PIM3 employs only four physiologic variables but includes six categorical variables that classify patients on the basis of reason for admission, use of mechanical ventilation in the first hour, and

diagnostic risk strata. PIM3 has not been extensively tested in the United States.

TABLE 9.2
Paediatric Index of Mortality 3 (PIM3) Variables and Model Coefficients

Score calculated based on variables collected from the time of initial patient contact to 1 hour after arrival in the pediatric intensive care unit.	
Variable	**Coefficients**
Pupils fixed to light? (yes/no)	3.8233
Elective admission (yes/no)	−0.5378
Mechanical ventilation in the first hour (yes/no)	0.9763
Absolute value of base excess (mmol/L)	0.0671
SBP at admission (mm Hg)	−0.0431
$SBP^2/1000$	0.1716
$100 \times FiO_2/PaO_2$ (mm Hg)	0.4214
Recovery post procedure?	
Yes, recovery from a bypass cardiac procedure	−1.2246
Yes, recovery from a nonbypass cardiac procedure	−0.8762
Yes, from a noncardiac procedure	−1.5164
Very high-risk diagnosis (yes/no)	1.6225
Cardiac arrest preceding ICU admission	
Severe combined immunodeficiency	
Leukemia or lymphoma after first induction	
Bone marrow transplant recipient	
Liver failure is main reason for ICU admission	
High-risk diagnosis (yes/no)	1.0725
Spontaneous cerebral hemorrhage	
Cardiomyopathy or myocarditis	
Hypoplastic left heart syndrome	
Neurodegenerative disease	
Necrotizing enterocolitis is main reason for ICU admission	
Low-risk diagnosis (yes/no)	−2.1766
Asthma is main reason for ICU admission	
Bronchiolitis is main reason for ICU admission	
Croup is main reason for ICU admission	
Obstructive sleep apnea is main reason for ICU admission	
Diabetic ketoacidosis is main reason for ICU admission	
Seizure disorder is main reason for ICU admission	
Constant	−1.7928

ICU, intensive care unit; SBP, systolic blood pressure.

Numerous obvious differences distinguish PRISM III from PIM3 (eg, interval for data collection, number of physiologic variables, inclusion of nonphysiologic data). The impact that these differences have on mortality prediction in the form of bias must be considered.[5,18] Foundationally, PRISM quantifies physiologic instability (PRISM III score) and uses categorical variables to facilitate accurate estimation of mortality risk while PIM only estimates mortality risk. PIM has not performed well in cardiovascular surgical populations where outcome is strongly associated with postoperative physiologic status.[18a] PIM3 uses a 1-hour (vs. 4 hours for PRISM III) PICU observation time, and this might imply it is potentially less affected by PICU therapies. However, the variable observation period before PICU admission could impose significant institution-level bias on the basis of the percent of patients transported to the PICU from other locations and the involvement of the PICU team in the transport or emergency department care. PIM3 includes a therapeutic intervention (mechanical ventilation) as a predictor variable that introduces bias from the prehospital and emergency department settings and introduces a therapy into the score when the use of the score to evaluate quality of care is closely related to the provision of therapy.

New Algorithms in the Public Domain

It should be clear to any practitioner of critical care that severity of illness and mortality risk are dynamic variables subject to a variety of influences such as therapies provided, presence of comorbidities, and evolution of the disease process. Although not designed to specifically predict mortality risk, there are severity of illness scores obtained over the course of PICU care that correlate with mortality risk. The Paediatric Logistic Organ Dysfunction (PELOD) score quantifies degree of organ dysfunction among six different organ systems—neurologic, cardiovascular, respiratory, renal, hematologic, and hepatic.[19] The score was developed from 594 patients and subsequently validated on 1806 patients demonstrating good discrimination of mortality (AUC = 0.91).[20]

Among the subgroup of infants admitted to the PICU or cardiac ICU following repair or palliation of congenital heart disease, efforts have been taken to ascribe risk of mortality based on surgical procedure and patient covariates. The Society for Thoracic Surgeons and European Association for Cardiothoracic Surgery (STS-EACTS) Congenital Heart Surgery Mortality Score was introduced in 2009. The score was developed on 77,294 procedures entered into the STS and EACTS Congenital Heart Surgery databases and validated on an additional 27,700 procedures.[21] Procedure-specific relative risks of in-hospital mortality were estimated for more than 140 congenital heart disease procedures. To combine procedure-specific risks with patient-specific factors, the patient's age, weight, and preoperative hospital length of stay were added to the model. The STS-EACTS score has good discrimination for in-hospital mortality (AUC = 0.816) and outperformed both the Risk Adjustment for Congenital Heart Surgery (RACHS-1) and the Aristotle Basic Complexity score in this cohort of more than 100,000 congenital heart disease procedures.

Next Generation: Morbidity and Mortality Prediction—Trichotomous Outcome

Morbidity Assessment

Although mortality adjusted for physiologic status and other case mix factors has been the core methodology of adult, pediatric, and neonatal intensive care assessments for decades, mortality for most pediatric critical illnesses has decreased since these methods were developed. More important, therapies are increasingly focused on reducing morbidity in survivors. However, most quantitative outcome assessment methods continue to focus on the dichotomous outcome of survival versus death.

A major challenge of pediatrics is the development of well-defined morbidity measures that are rapid, reliable, and objective; measure the child's status at the time of testing; and are applicable to a broad range of ages in a variety of environments. In-depth testing such as neuropsychologic methods will remain the clinical standard, but other methods applicable to all pediatric ages and sufficiently rapid to be used in large samples are necessary. The Glasgow Outcome Scale score was adapted to children in the Pediatric Cerebral and Overall Performance Category scores (PCPC/POPC), but sufficient inter-rater reliability was only achievable when

neighboring categories were combined[22]; therefore using these scores in outcome studies risked requiring very large sample sizes to detect significant differences. The history of outcome studies in adult medicine demonstrated the value of scales such as the activities of daily living scale. Such a functional status measure would enable researchers to track the trajectory of disease and recovery and might enable us to project future functional status, resource needs, economic impact, and other effects of illness in large numbers of patients. Thus the foundation of the Functional Status Scale (FSS) was to adapt the concepts of activities of daily living to pediatrics in a manner that met the criteria described earlier.[4]

The FSS was developed through a formal consensus process by pediatric health care specialists from 11 institutions, including pediatricians, neurologists, developmental psychologists, physiatrists, nurses, respiratory therapists, and intensivists. The FSS is composed of six domains including respiratory status, feeding, motor functioning, communication, sensory functioning, and mental status. Each domain is objectively assessed from normal to very severe dysfunction. The score was composed to enable it to be assessed from the parents' or caregivers' reports or medical records. It was validated on more than 800 patients from seven institutions against an adaptive behavior scale, has very good inter-rater reliability, and has been used in numerous studies including a study of more than 10,000 pediatric patients. Comparisons with the POPC and PCPC demonstrated FSS increases with each higher POPC and PCPC category. However, the dispersion of the FSS scores indicated a lack of precision in the POPC/PCPC system when compared with the more objective and granular FSS system.[23]

A recent multisite study of more than 5000 pediatric ICU patients demonstrated the importance of the development of new functional status morbidities during intensive care.[24] The rate of new functional status morbidities assessed by an increase of 3 or greater in the FSS score was 4.8%, twice as high as the rate of hospital deaths. On hospital discharge, the good category decreased from a baseline of 72% to 63%, mild abnormality increased from 10% to 15%, moderate abnormality status increased from 13% to 14%, severe status increased from 4% to 5%, and very severe was unchanged at 1%. The highest new morbidity rates were in the neurologic diagnoses (7.3%), acquired cardiovascular disease (5.9%), cancer (5.3%), and congenital cardiovascular disease (4.9%). New morbidities occurred in all ages, especially in those younger than 12 months of age. New morbidities involved all FSS domains with the highest proportions involving respiratory, motor, and feeding dysfunction.

The recent data compared with historical data suggest that pediatric critical care may have exchanged mortality for morbidity over the past several decades. Although it is not possible to precisely compare the rates over time because of the different research methods, data from the 1990s demonstrated a PICU mortality rate of 4.6% and a PICU morbidity rate of 3.1% (based on a ≥2 POPC change) while the current demonstrated a hospital mortality rate of 2.4% and morbidity rate of 4.8%. Thus the “morbidity and mortality rate” decreased from only 7.7% to 7.2% as the mortality rated decreased and the new morbidity rate increased. Because these rates are not severity or risk adjusted, the changes in admission criteria and other factors that have occurred in the past several decades could have also significantly influenced this comparison.

Recently the Collaborative Pediatric Critical Care Research Network multisite study demonstrated that new functional status morbidities associated with PICU

stays present on hospital discharge are associated with many of the same factors as mortality, including physiologic status measured by the PRISM III score, age, admission source, and diagnostic factors.[25] Importantly, these new morbidities when measured with the FSS score can be modeled simultaneously with mortality. Critical care mortality is usually associated with physiologic abnormalities in the cardiovascular, respiratory, neurologic, and hematologic systems. It appears that new morbidity significantly affecting functional status is often an event along the path toward mortality as both outcomes are strongly associated with the degree of physiologic alterations. Trichotomous modeling uncovered the phasic association of morbidity risk with physiologic status; morbidity risk increases with physiologic instability but then decreases as patients with potential morbidity die. Recent studies indicate that trichotomous logistic regression can produce a well-performing model for simultaneous prediction of both morbidity and mortality suitable for risk adjustment in research, quality, and other studies.

The inclusion of morbidity and mortality in outcome prediction has wide implications for research trials and quality programs, especially those currently based on internal or external benchmarking of standardized mortality ratios. Care assessments that focus on morbidity and mortality will have wide appeal and relevance. Potentially, evaluations of, and improvements in, the structure and process of care analogous to those resulting from the investigations of the variability of standardized mortality ratios could result from the inclusion of this important new outcome. Initiatives that monitor standardized mortality ratios could find relevance in the inclusion of standardized morbidity ratios as well.

Application of Prediction Tools in Pediatric Intensive Care

Prediction tools can be applied at both the population and individual patient levels. At the population level, prediction tools are used in benchmarking, which is a process in which the performance of entities (eg, individuals, PICUs, institutions) is observed and then compared with internal or external standards. Clinical scoring systems (eg, PRISM III) are used to control for severity of illness and other factors, thus allowing for standardized comparisons. The two most common standardized comparisons used in pediatric intensive care are the standardized mortality ratio (observed mortality rate divided by the expected mortality rate) and the standardized length-of-stay ratio (observed length of stay divided by the expected length of stay).

Internal benchmarking is distinguished from external benchmarking as it relates to the comparison of performance within the entity. For example, an individual PICU may want to compare the impact of a new care protocol on length of stay as compared with the current internal standard of care for a particular illness. Calculating a standardized ICU length-of-stay ratio would allow for the comparison of practices while accounting for differences in patients' severity of illness between the two groups. External or competitive benchmarking allows for the direct comparisons between individual hospitals or PICUs by controlling for differences in case mix.

At the individual patient level, the uses of prediction tools for short-term outcome are varied. Clinical scoring systems are often employed in clinical trials and

outcomes analyses to control for patient severity of illness or in measuring changes in physiologic status after a novel therapy has been initiated.[5]

Future Directions—Prediction Tools for Decision Support

The use of computerized decision support in adult, pediatric, and neonatal ICUs has grown considerably over the past several years. The integration of alerts, reminders, and protocols into computer order entry systems can help in guiding therapy and the reduction of medication errors.[26] There is, however, still a paucity of effective and validated decision support tools to guide the critical care practitioner in making real-time decisions that affect short-term patient outcomes. The use of continuous monitoring data in the ICU to predict clinical deterioration is a recent subject of great interest. Moorman and colleagues[27] developed a predictive algorithm for clinical deterioration in very-low-birth-weight infants employing heart rate characteristics monitoring and demonstrated, in a randomized clinical trial of 3003 patients, a 20% relative reduction of mortality with a number needed to monitor of 48. Efforts to develop predictive monitoring algorithms in older children and adults are under way.

The increasing availability of large pediatric critical care datasets potentially provides the foundation for the creation of decision support tools. The various pediatric critical care data sources in the United States and worldwide vary greatly as they relate to accessibility/cost, clinical detail, and represented population.[28] The expectation of the National Institutes of Health that federally funded investigators make their data widely and freely available to the public will only increase the amount of available data. Currently, datasets generated from research conducted by the CPCCRN and the Pediatric Emergency Care Applied Research Network are available to researchers. The Pediatric Existing Data Analysis group of the Pediatric Acute Lung Injury and Sepsis Investigators maintains a regularly updated list of pediatric critical care data sources (http://pedal.vpicu.net/datasources.html).

CHAPTER 10

Long-Term Outcomes Following Critical Illness in Children

Francois Aspesberro, Jerry J. Zimmerman, R. Scott Watson

PEARLS

- Development of specialized pediatric intensive care has contributed to substantially reduced mortality for critically ill children.
- Publications suggest that pediatric critical care may have "exchanged" decreased mortality for increased long-term morbidity, with children struggling to perform at their premorbid levels following a PICU stay.
- The post–intensive care syndrome, first described in adults, may also occur in this vulnerable population of children.
- Research has identified physical, cognitive, and mental health domains as the major areas of impairment in survivors of critical illness.
- There is an urgent need for additional research to better characterize post–intensive care morbidity and its risk factors with the goal of minimizing adverse sequelae associated with critical illness.

As pediatric intensive care has become progressively more effective at sustaining life during hospitalization for critical illness, a wide range of long-term detrimental sequelae among survivors is becoming apparent. For intensivists, a comprehensive understanding of the long-term effects of critical illnesses and critical care therapies is essential for the design of interventions to improve care and enhance the lives of patients and their families who experience life-threatening illness and injury.

Mortality Reduction: The First Frontier for Critical Care Medicine

Mortality reduction was the first frontier of critical care medicine and remains the

most commonly used measure of outcome following critical illness. Fortunately, the subspecialty of pediatric critical care has matured considerably, and mortality rates have decreased substantially (Fig. 10.1).[1-4] Mortality rates as low as 3% were reported for 80,739 children included in the Virtual Pediatric Intensive Care Unit (PICU) Systems database, who were admitted to PICUs between 2005 and 2008.[5] Despite low overall short-term mortality, some children surviving critical illness remain at increased risk of death following hospitalization. Most notably, children *surviving* hospitalization for severe sepsis have mortality rates 2 to 50 times greater than that of the general population, depending on age and gender.[6]

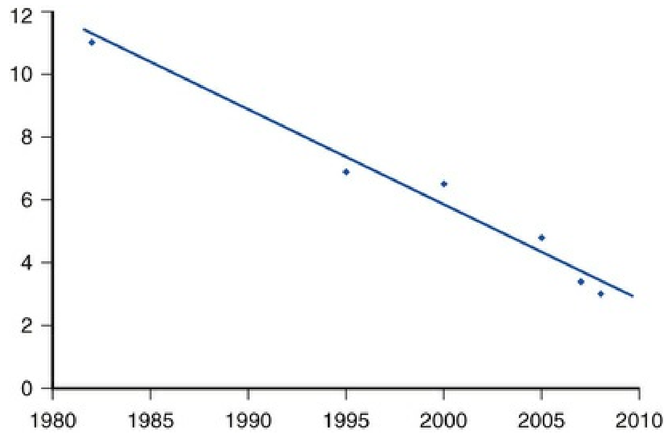

FIG. 10.1 Historical decline of PICU mortality.

Mitigating Long-Term Morbidity: The Next Frontier for Pediatric Critical Care Medicine

Unfortunately, many children surviving critical illness struggle to perform at their preillness levels. Thus, improvements in mortality have not necessarily led to concomitant reductions in morbidity. Increases in survival and morbidity have suggested to some that pediatric critical care has exchanged mortality for morbidity.[7,8] Although this may have been an unavoidable consequence of initial success in improving survival from life-threatening illness, the next frontier for the field is to understand the antecedents of this morbidity so that it can be prevented whenever possible and minimized when it does occur.

Post–Intensive Care Syndrome

Post–intensive care syndrome (PICS) is defined as new or worsened problems in cognitive, psychiatric, or physical function in a patient following a critical illness that persist beyond acute care hospitalization.[9] In addition to patients, family members themselves are also at risk of developing a variant of this syndrome, PICS-Family, with psychiatric symptoms, such as depression, posttraumatic stress, anxiety, or complicated grief. PICS has been described in adults surviving critical illness, but research in the area of pediatric PICS is currently lacking, and its incidence in children remains unknown. Nonetheless, it provides a useful conceptual framework

for morbidity among pediatric survivors of critical illness, who, like adult survivors, are at risk of long-term impairment in multiple domains, including physical, cognitive, social, and emotional functioning[10] (Fig. 10.2).

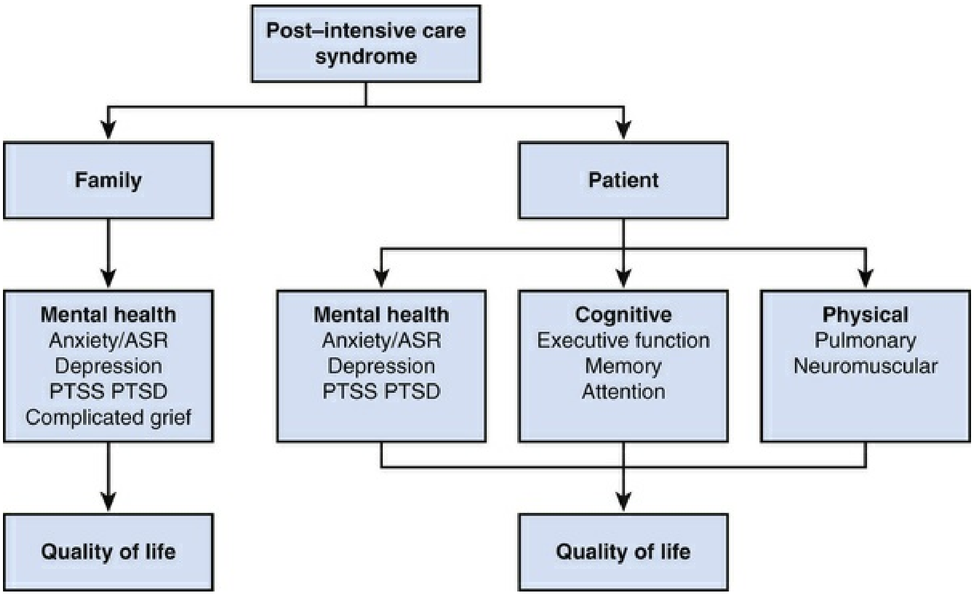

FIG. 10.2 Post–intensive care syndrome.

Impact of Pediatric Critical Illness on Health-Related Quality of Life

Children surviving critical illness incur elevated risk of postdischarge mortality and morbidity, with impairment in physical, cognitive, emotional, and social function, as well as overall health-related quality of life (HRQL) (Table 10.1).[1,11-16] Patients' families also suffer emotional, financial, and social strains, which, in turn, can make it more difficult for them to support the recovery of their children. The assessment of HRQL has gained increased consideration in patients surviving after critical illness.[17,18] Baseline HRQL[19] is determined by genetics[20]; parent, family, and home characteristics[21]; and chronic, comorbid conditions.[22,23] In addition to the effects of acute illness,[24] these same variables likely impact HRQL recovery following critical illness. In assessing HRQL among a generalized sample of US children >6 years of age (60,031 children included in the 2003/2004 National Survey of Children's Health), lower HRQL was noted for children in lower socioeconomic status groups, those with health care access barriers, adolescents compared with children, and individuals with chronic medical conditions.[25]

TABLE 10.1

Domains of Long-Term Outcomes and Examples of Morbidity Following PICU Discharge

Domain	Morbidity Example
Physical	Neuromuscular weakness
	ICU-associated polyneuropathy

	Pain
	Disturbed sleep patterns and nightmares
	Pulmonary morbidity
Cognitive	Executive function
	Processing speed
	Memory
	Attention
	Academic performance (lifelong effects)
Mental health	Anxiety
	Depression
	Acute stress disorder Posttraumatic stress disorder (PTSD)
Family	Mental health of parents and siblings Divorce
Social	Reduced ability to interact with peers Missed school Family Isolation from friends and family members
Economic	Costs of care Loss of income due to missed work or job loss

In 1995, Wilson and Cleary published a conceptual model of patient outcomes linking clinical variables with HRQL (Fig. 10.3).[26] Individual characteristics include personality traits, chronic comorbid conditions, and genetics. Environmental characteristics include parental stress, family dynamics, and home demographics. Critical illness includes the intensity and duration of organ system dysfunction.

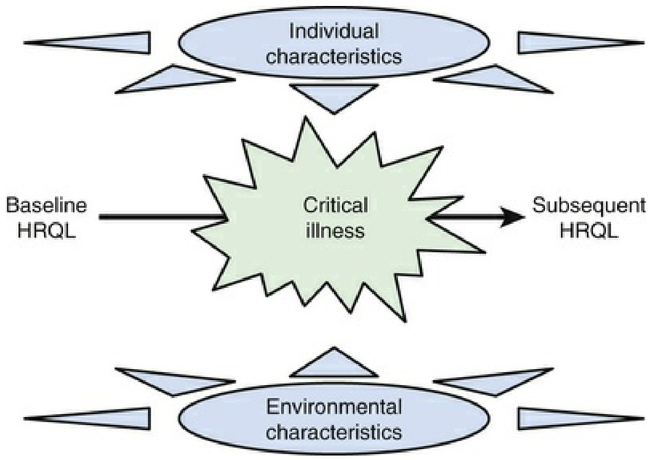

FIG. 10.3 Individual characteristics and environmental characteristics.

As early as 1948, the concept of maximizing quality of life as a fundamental right was included as one of the basic principles in the World Health Organization's Constitution through the statements, “Health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity” and “The enjoyment of the highest attainable standard of health is one of the fundamental rights of every human being” (World Health Organization, 1949, p. 1).[27,28] Quality of life is defined as an individual's perception of his or her position in life, in the context of the culture, environment, and value systems in which the person lives and in relation to the individual's goals, expectations, standards, and concerns.[11,29] HRQL is defined as quality of life in which a dimension of personal judgment over one's health and disease is added.[30,31] In the case of children, HRQL is influenced by factors such as the ability to participate in peer groups and the ability to keep up with developmentally appropriate activities. It provides a broad view of child

health, encompassing aspects of perceived health, health behavior, and well-being.[27,25,32]

Outcomes Following Cardiopulmonary Resuscitation

Ebrahim and colleagues reviewed the effects of resuscitation intensity, illness severity, and baseline disease on adaptive behavior and functional outcomes on HRQL of children urgently admitted to a PICU.[33] This study found that more intense modes of resuscitation and increasing severity of illness were independently associated with the development of acquired brain injury and reduced HRQL. Higher severity of illness was found to correlate with worsening HRQL 6 months after discharge but not at 2 years.[34] However, not all the studies are in agreement; some have not found an association between measures of severity of illness and HRQL among survivors of pediatric intensive care.[14,35]

Outcomes for Long-Stay Pediatric Intensive Care Unit Patients

Since the mid-1990s, the demographics of children admitted to PICUs have changed, with admission of more children with multiple chronic problems, increased readmission rates, and a growing number of children who stay in the PICU for longer periods of time.[36] Conlon and associates assessed HRQL 2 to 10 years after PICU discharge for 193 children who required at least 28 days of pediatric intensive care.[1] Impaired HRQL was found in 43% of the PICU survivors, of whom 20% had poor HRQL with persistent disabling health problems.

Outcomes Following Pediatric Severe Infection

Severe infections such as meningococcemia and other forms of sepsis are associated with high morbidity. Children surviving meningococcemia exhibit impaired HRQL, especially within the physical domain, up to 3 years after discharge from a PICU.[37,38] In meningococcal septic shock, less favorable scores on behavioral and emotional measurement scales were significantly also associated with poorer HRQL.[38] Similarly, in a cohort of children in urban Senegal surviving bacterial meningitis, HRQL scores were significantly lower than controls.[39]

Als and coworkers published a prospective neuropsychologic function study of school-aged children who survived meningoencephalitis, sepsis, and other disorders.[40] Admission to PICUs was followed by deficits in neuropsychologic performance and educational difficulties, with more severe difficulties noted following meningoencephalitis and septic illness. Their results show that in the 3 to 6 months following discharge from intensive care, school-aged children significantly underperform on measures of neuropsychologic function. Analysis of the effect of illness type on outcome revealed that aspects of neuropsychologic function, such as memory function, and teacher-rated academic performance were most reduced in children with meningoencephalitis and septic illness. Multivariable linear regression revealed that worse performance on a composite score of neuropsychologic impairment was more prevalent when children were younger, from a lower social class, and had experienced seizures during their admission ($p < 0.02$).

Farris and colleagues reviewed the functional outcome of 384 children who survived severe sepsis employing the Pediatric Overall Performance Category score.[41] Thirty-four percent of survivors had a decline in their functional status at 28 days, and 18% had poor functional outcome. Clinical factors associated with increased risk of poor outcome included central nervous system infections, intraabdominal infection, a history of recent trauma, requirement for cardiopulmonary resuscitation, and high PRISM III score. Decline in functional status 28 days after onset of severe sepsis is a frequent and potentially clinically meaningful patient-centered outcome. The duration of follow-up in this particular cohort was relatively short. Longer duration of follow-up would provide an improved sense of the severity and duration of morbidity experienced by survivors of pediatric sepsis. It would also provide an indication of the proportion of patients that return to their baseline functional status and how much time is required to achieve this result.

Outcomes Following Pediatric Acute Respiratory Distress

Children with acute respiratory distress (ARDS) continue to have high short-term mortality, especially those with comorbid conditions such as an immunocompromised state or sepsis.[40] Little knowledge of long-term outcomes exists for children who survive pediatric ARDS. Significant long-term effects reported in adult ARDS survivors include diminished lung function, decreased exercise tolerance, and reduced neurocognitive function that impact daily living and decrease quality of life.[42-47]

Pediatric Traumatic Brain Injury: A Model for Multidisciplinary Outcomes Assessment

Pediatric traumatic brain injury is an example of the need for multidisciplinary outcomes assessment and intervention after pediatric critical care. A leading cause of death in childhood, major trauma also leads to long-term morbidity among the 80% who survive the acute hospitalization.[32,48-50] Parent proxy reports 2 years after injury showed that injured children and adolescents continue to have significantly worse motor functioning, autonomy, cognition, and social functioning, and significantly fewer positive emotions than the normative sample, even after controlling for age, gender, and maternal socioeconomic status.[27] Child self-reports showed fewer physical complaints but more motor function and autonomy deficits. Holbrook and coworkers found that a high proportion of adolescents hospitalized with an injury screened positive for acute stress disorder, and this negatively impacted HRQL outcomes during the first 2 years after injury.[51] More attention has been focused on the psychosocial effects of injury on a child's health and well-being. Not only is it important to measure the impact an injury has on the child's psychosocial health during a defined period after the injury, but it is also important to analyze the developmental implications of the injury on the child's future well-being. HRQL measurements can play a valuable role in documenting the recovery trajectory after different types of injuries, including traumatic injury.

Antecedents and Variables Associated With Outcomes

Effect of Chronic Comorbid Conditions on Outcomes Following Critical Illness

Chronic conditions are common among children admitted to US PICUs, occurring in up to 52% of admissions.[52] Children with preexisting comorbid conditions may be particularly vulnerable to long-term adverse outcomes, as such children demonstrate greater risk for PICU admission in general, greater injury from a given insult, and increased lasting morbidity following illness.[22,34,37,53-59] Such children are at increased risk for multiple organ dysfunction syndrome (MODS) and increased PICU mortality. Nonetheless, children with chronic diagnoses seem to be just as likely as previously healthy children to return to their baseline functional status after MODS. Of note, return to baseline functional status varies by chronic illness category. Patients with congenital heart disease and those who receive solid organ transplants have higher rates of functional outcomes improvement than their healthy counterparts. This initially counterintuitive finding is most likely due to resolution of chronic organ dysfunction following operative cardiac repair or organ transplantation.

Effect of Parent, Family, and Home Characteristics on Outcomes Following Critical Illness

Children are dependent on their families for their physical, emotional, and social needs, and family characteristics can significantly influence children's HRQL. Multiple contextual factors related to the home environment influence outcomes following illness. Higher maternal education has been shown to contribute significantly to better child HRQL,[60] whereas lower paternal education resulted in lower child HRQL.[27] Socioeconomic status (SES) has repeatedly been demonstrated as an important determinant of health and mortality: The lowest SES is associated with the poorest outcomes.[61-67] In addition it is important to note that SES may change during the evaluation period of a longitudinal study as the family copes with lost work time and expenses related to medical care.

Parents of PICU survivors may have psychologic sequelae affecting their own quality of life.[11] Reduced parental physical and psychosocial well-being has been shown to consistently predict poorer child adjustment.[67-71] Among ICU survivors, psychologic morbidity, including anxiety and depression among family members, affects patient outcomes, including critical decision making by the patients.[72] Not surprisingly, highly functioning, adaptive families have better HRQL after a child survives critical illness.[48] Also not surprisingly, poor psychologic outcome is greater in parents who have poor baseline mental health, family functioning, coping skills, and social support, who perceive greater severity of illness in their child, or who have witnessed their child being injured.

Association Between Posttraumatic Stress Disorder and Health-Related Quality of Life

Multiple studies identify an inverse relationship between posttraumatic stress disorder (PTSD) and HRQL following critical illness, demonstrating the psychologic impact of illness and injury on long-term HRQL.[13,14,27,51,73-82] Preliminary studies in

adults have shown that reduction in PTSD symptoms may be associated with improvements in HRQL.[83] Consideration should be given to providing psychologic support for children, adolescents, and parents after PICU admission. Reliable diagnosis and efficacious treatments for PTSD are available and could potentially lead to beneficial interventions for children and adolescents at risk.[84,85]

Exposure to Invasive Technology

Children hospitalized in PICUs are subjected to highly invasive interventions often necessary to overcome the critical period of their illness, yet little is known about their subsequent psychologic adjustment.[86] Rennick and colleagues followed 120 children for 6 months after PICU and ward discharge.[74] Children who were younger, most severely ill, and who endured more invasive procedures had significantly more medical fears, a lower sense of control of their health, and ongoing posttraumatic stress responses for 6 months postdischarge. These findings indicate that invasiveness coupled with length of stay and severity of illness in young children may have adverse long-term effects. Newburger and associates showed that increased length of stay in infants during hospitalization for arterial switch was independently associated with decreased intelligence quotient (IQ) at 8 years of age (1.4 IQ points lower for each additional day in the ICU between 3 and 13 days).[87]

Metrics for Patient-Centered Outcomes: Functional Status and Health-Related Quality of Life

With improved survival, new disease patterns have emerged related to long-term complications of critical illness and its treatment. As noted earlier, historically, the management of pediatric critical illness focused on survival as the primary goal, and it is still the most commonly used determinant in outcome studies after intensive care.[1,27] Once survival rates improved, the physical, mental, and HRQL sequelae of critical illness began to appear.[1,2,26-28,48] HRQL and functional status (FS) represent clinically meaningful outcome measures for children surviving critical illness. Validated pediatric HRQL and functional status measures are now available and should be used in research that examines how pediatric critical care practitioners can maximize recovery among children surviving critical illness.[88]

Ideal Health-Related Quality of Life Outcome Measure

HRQL instruments should provide reliable and valid measures that can quickly and easily be used to quantify morbidity or disability after a child's critical illness or injury. These tools need to be multidimensional and include, at a minimum, the physical, mental, and social health domains outlined by the World Health Organization.[1,89] Ideal HRQL questionnaires should measure all the health dimensions relevant to the studied patient population and preferably be completed by the children themselves (≥6–8 years of age).

When selecting an HRQL instrument, it is important to consider the following six factors[32,48,90]:

- *Psychometric properties*. Reliability consists of internal consistency and reproducibility. Validity assesses the extent to which an instrument measures the construct it is intended to measure.
- *Responsiveness or sensitivity to change*. Does the instrument detect change after an intervention over time? Responsiveness is examined in longitudinal studies that compare the outcomes of a group expected to change to another group that is not.
- *Interpretability of HRQL scores*. It is important to be able to translate a quantitative score or change in scores to a qualitative category or to an external measure that has a familiar meaning. An instrument's interpretability is enhanced when there are normative data from a representative sample of the general population or data from patients with specific clinical conditions.
- *Response burden*. The time, effort, and other demands that are placed on the respondent who is completing the instrument will affect the outcome. Completing the instrument should not create undue physical or emotional strain on the respondent.
- *Mode of administration*. Self-report is considered the gold standard in HRQL measurement, and children are assumed to have unique awareness of their own health. Most of the HRQL instruments have both child and proxy versions; however, the age at which self-report is available varies among the instruments. Proxy investigation is second best because proxy reports do not always correspond with self-evaluations, particularly with regard to internal factors, such as emotions.
- *Instrument adaptation*. Practitioners should consider if the instrument has been adapted or translated for use with children who differ from the original population for which it was developed in terms of culture or language.

Performance and Shortcomings of Health-Related Quality of Life Tools

Table 10.2 (eSupplement) contains a list of 22 HRQL measures that have been used in the pediatric critical care studies.[88] This table summarizes the most important psychometric properties of these tools. The majority of the referenced studies used HRQL assessment tools that are far from ideal. Although most of these studies reported construct validity, only a few included the most important characteristics, such as proxy report, age range, time/effort burden, and sensitivity to change over time. Some of the best instruments for assessing HRQL that are currently available are the PedsQL 4.0 generic core scales, KIDSCREEN-27, the 28-item short child health questionnaire parent form (CHQ-PF28), and KINDL. These tools are offered as both self and proxy reports, cover a wide age range of children, are brief with a low response burden, are multidimensional, and have been shown to have internal consistency and test-retest reliability, as well as sensitivity to change over time, and content and construct validity.

TABLE 10.2

Performance and Shortcomings of Health Related Quality of Life (HRQL) Assessment Tools (eSupplement)

Novel Approaches to Improving Long-Term Outcomes for PICU Survivors

Pediatric intensivists must lead the effort to better understand and optimize long-term outcomes through clinical practice, research, and advocacy. All pediatric critical care practitioners should actively acknowledge and address the long-term physical, cognitive, and mental health impact of critical care on their patients. To better understand and optimize long-term outcomes, critical care practitioners must engage in clinical research in these areas. Such research should include information about the ICU course, as well as surrounding events, such as preexisting comorbidities, reason for admission, and illness severity. There is an urgent need for follow-up programs to study the intensity and duration of the morbidity burden following critical illness, as well as to develop novel interventions aimed at maximizing long-term outcomes.

Outcomes Assessment Program

In January 2010, Seattle Children's Hospital (SCH) developed and launched one of the first outcomes assessment programs (OAPs) in the United States. The OAP is designed to measure patient- and family-centered outcomes of care on all children admitted to SCH. The program accomplished this goal by assessing two key patient-centered outcomes: HRQL and family experiences with care. Families and patients are asked to score HRQL and functional status[91] at the time of admission and then again 4 to 12 weeks after discharge. The National Research Corporation (NRC) Picker Family Experience Survey (FES) is administered at the time of discharge to assess family experience with care.[92] The main objective of conducting these measurements is to allow the hospital to better understand and improve on the HRQL and care experiences of the populations it serves. The OAP was developed with multistakeholder input and has a steering committee that includes quality of care researchers, physicians, nurses, and an ethicist, as well as families and interpreters. Although no direct benefit of the program has yet been established, Dasai and colleagues demonstrated that HRQL measurement was associated with a more traditional, objective outcomes commonly used to measure the effectiveness of quality improvement interventions.[93]

Follow-Up Programs for ICU Survivors

Aside from recommendations from the Pediatric Acute Lung Injury Consensus Conference for the care of children after pediatric ARDS,[94] there is currently no other specific guidance in place for follow-up of survivors of pediatric critical illness. Long-term outcomes assessment should be incorporated in follow-up programs of PICU survivors, and it should form part of the gold standard of critical care delivery.

Pediatric intensivists and psychologists should be involved as core members of follow-up teams. In 2011, the Indiana University School of Medicine opened one of the first collaborative care clinics aimed at meeting the recovery needs of adult ICU survivors in the United States.[95] The mission of the clinic is to maximize the cognitive, physical, and psychologic recovery of ICU survivors via patient and caregiver needs assessment and a follow-up visit that includes a family conference. Preliminary data from 53 patients showed that only 12% had normal cognition. The three most common diagnoses at follow-up were ICU-acquired cognitive impairment, depression, and dyspnea. The average time between visits was 2.5 months. Significant core improvements were seen in functional and cognitive domains but not in the behavioral-psychologic domain.

Innovative Trichotomous Outcome Model

Assessment of longer-term mortality, morbidity, and patient-centered outcomes is increasingly necessary.[96] Pollack and coworkers developed a new tool that combines the Functional Status Scale (FSS) and components of the Pediatric Risk of Mortality (PRISM) III score to determine if death and important nonmortal short-term outcomes can be predicted simultaneously, based on physiologic and other data available shortly after PICU admission.[96] This trichotomous outcome model is unique in that it has the potential to provide a benchmark for in-hospital morbidity as well as mortality. It might be expanded in the future to include long-term outcome. It predicts three possible outcomes: death, intact survival, and survival with new functional disability. Although the FSS was not designed for use in individual patients, further studies of the wider patient and family impact of a change in FSS score, including the relationships of FSS to HRQL, future health care use, and postdischarge function and recovery, will be essential to understand the full implications of new morbidity identified with the FSS.[97]

Research Aims[98]

The traditional 28-day mortality outcome used in clinical trials of sepsis, ARDS, trauma, and many other critical illnesses does not account for important long-term sequelae of critical illness. Some studies have examined children's outcomes during the first year following PICU discharge, but relatively little is known about their long-term outcomes. Future trials should include long-term outcome measurements, as well as mortality and HRQL/functional status, to truly understand the full impact of critical illness in children. There is a need for well-designed, prospective, longitudinal studies with serial assessments that will satisfy the following objectives:

- Identify PICU survivors most at risk.
- Characterize long-term outcomes.
- Generate recovery curves for various illnesses.
- Identify factors associated with long-term morbidity and recovery.
- Define potential targets for intervention.

Potential Targets for Interventions

Many adverse sequelae of critical illness and critical care are amenable to intervention. Acute loss of skeletal muscle mass, which is greatest in patients with multiorgan failure, contributes to the ongoing physical disability common among survivors of critical illness.[99,100] Early and more aggressive physical therapy and passive range of motion introduced in the ICU may reduce ICU neuropathy and other musculoskeletal complications, but the ability to stratify risks and tailor programs to individual needs requires further study. As sleep is known to be severely disturbed in the hospital, interventions that improve the quality of sleep may reduce cognitive and psychiatric sequelae.[101,102] Delusional memories are reported by almost a third of children surviving critical illness. These can be exacerbated by exposure to opiates and benzodiazepines, and they are associated with an increased risk of PTSD.[13] The pharmacologic milieu encountered during critical illness is a blend of potent neurologically active drugs that may facilitate transition to delirium. Interventions such as memory books and journals kept by family members may facilitate reintegration into life after critical illness.[103-106]

Psychologic impairments such as depression are prominent and important features of PICS.[107] Critical illness and its outcomes affect not only critically ill children but also their families. There is an increased risk of mental health disorders, such as anxiety, depression, and posttraumatic stress disorder, in the families and caregivers of PICU survivors.[108-112] Psychologic support may improve outcomes in children and parents alike. There is a need to understand the risk factors of increased care provider burden and worsened family dynamics that PICU survivor families face. Further research is essential to establish the optimal timing, extent, and type of psychologic support for these children and families.

Conclusions

Critical care practitioners are classically trained in resuscitation science that is detailed throughout this textbook. Historically this has been associated with a marked decrease in mortality associated with childhood critical injury and illness (see Fig. 10.1). There has been greater recognition that critical care begins and ends outside the walls of the intensive care unit. Intensivists and their care-provider colleagues are increasingly aware of the impact of genetics, family dynamics, home environment, and preexisting comorbidities on the intensity, duration, and outcome of critical illness. Although the critical care team may be acutely interested in duration of shock, length of mechanical ventilator and dialysis support, new or progressive organ dysfunction, and PICU and hospital resource utilization, these are surrogate outcomes that may or may not be associated with durable, clinically meaningful, patient-centered outcomes.[113] With maturation of the field of pediatric critical care medicine, critical care practitioners now have the opportunity as well as the obligation to look beyond PICU discharge with a goal of minimizing not only mortality but also the burden of long-term morbidity in accordance with patients' and families' expectations. Ultimately, maximizing long-term functional status and health-related quality of life should be the most important goals of critical care medicine.

CHAPTER 11

Safety and Quality Assessment in the Pediatric Intensive Care Unit

Matthew C. Scanlon, Martin Wakeham

PEARLS

- The six domains of quality in the pediatric intensive care unit are safety, effectiveness, patient centeredness, timeliness, efficiency, and equity.
- Research demonstrates that errors in health care are often caused by poorly designed systems of care.
- Three essential activities of a patient safety program include risk identification, risk analysis, and risk reduction.
- Safety science distinguishes between the reactive, people-focused Safety I (akin to quality assurance work) and the proactive, systems-focused Safety II.

Recognition of the importance of quality improvement and patient safety for pediatric intensive care units (PICUs) has been steadily increasing, and there have been some provocative and important additions to the world of safety and quality that have particular relevance for PICUs. Of note, increasingly it appears that the worlds of patient safety, quality improvement (QI), and safety science are divergent. This statement may seem counterintuitive, if not even heretical. This chapter articulates the rationale for this statement and explores the implications for pediatric critical care.

Brief Consideration of the Relationship Between Safety and Quality

Both the Institute of Medicine (in its report *Crossing the Quality Chasm*) and conventional wisdom suggest that quality and patient safety are related, with the latter being one of the six domains of the former (Table 11.1). Based on this report, safety is a prerequisite to achieving quality. That is, it is impossible to achieve true quality without improving safety. Those who argue that attention to other aspects of quality beyond safety is critical still confirm this observation.[1] For the pediatric critical care provider, the important point is that safety is a necessary prerequisite for quality, but improving safety is insufficient to achieve quality.

TABLE 11.1

The Institute of Medicine's Six Domains of Quality

Domain	Definition	PICU Example
Safety	Freedom from preventable harm during care[2]	Prevention of central line–associated infections
Effectiveness	Providing services based on the best available scientific knowledge in order to achieve the best outcome	Following American College of Critical Care Medicine guidelines for hemodynamic support of pediatric and neonatal patients in septic shock[72]
Patient/family centered	Provision of care in a manner that is respectful of and responsive to individual patient preferences, needs, and values	The presence and involvement of parents on rounds[73]
Timeliness	The reduction of waiting and potentially harmful delays for both those who give and receive care	Timely administration of antibiotics and fluids in septic shock
Efficiency	Achieve adequate outcomes while keeping resource utilization appropriate, thus minimizing cost	Reduction of length of stay without increasing unplanned readmissions
Equity	Quality of care provided in the PICU should be independent of characteristics such as gender, ethnicity, geographic location, and socioeconomic status	Risk-adjusted mortality and resource utilization for critically ill children did not differ according to race, gender, or insurance status; however, uninsured children had significantly greater physiologic derangement at time of PICU admission[74]

Although the fundamental relationship between quality and safety remains unchanged, there appear to be important differences between the methods necessary for QI and those necessary for achieving safety, depending on the context of care. Because the PICU is one of the settings where this distinction may have tremendous impact, it is imperative that intensivists understand the differences. These will be discussed in the section titled "Fundamentals of Patient Safety With an Introduction to Safety I and Safety II."

State of Safety and Quality in Pediatric Intensive Care Units

Since 1999 when the Institute of Medicine's report *To Err Is Human* drew recognition to the scope of preventable medical harm,[2] there have been dramatic changes in how quality and safety are managed in PICUs. These include the continued existence of PICU-specific quality measures endorsed by the National Quality Forum (Table 11.2), a dramatic reduction in central venous catheter–associated bloodstream infections (CA-BSIs), and engagement of intensivists in the work of the Solutions for Patient Safety (SPS) collaborative[3,4] Although data on the SPS collaborative do not provide PICU-specific results, the self-reported data indicate that, since 2012, the collaborative has saved more than 4700 children from serious harm while saving

greater than $92 million. PICU-related areas of improvement include ventilator-associated pneumonia (VAP), CA-BSI, catheter-associated urinary tract infections (CAUTIs), and venous thromboembolism. These results reflect the creation of standardized bundles of care, which then were implemented at participating children's hospitals.

TABLE 11.2

Endorsed Pediatric Intensive Care Unit Measures

Measure	Description
PICU standardized mortality ratio	The ratio of actual deaths over predicted deaths for PICU patients, adjusted using an accepted risk of mortality tool
PICU severity-adjusted length of stay	The number of days between PICU admission and discharge for patients, adjusted using an accepted risk of mortality tool
PICU rate of unplanned readmissions within 24 hours of PICU discharge	The total number of patients requiring unscheduled readmission to the PICU within 24 hours of discharge or transfer, over the number of discharges and transfers

Although the SPS work has focused on what can be described as the creation of topic-specific improvement bundles, implementation of the bundles, and then quality assurance work, it largely does not reflect either a systems-focused approach or what will be described as Safety II.

Fundamentals of Quality Improvement and Patient Safety: Systems Thinking

To understand patient safety and quality in health care, one first must recognize the importance of systems to the way care is delivered. The Institute of Medicine, drawing from James Reason's studies of errors, defines a system as “a set of interdependent elements interacting to achieve a common aim.”[2] One model of systems in health care consists of five interaction components: (1) people (2) use tools and technologies (3) to perform tasks (4) within an environment (5) in the context of an organization.[5] Each of these five components interacts with the others to yield the emergent properties (greater than the sum of the parts) of safety and quality.

Several essential implications follow from this model. First, no matter how safe any component is (eg, an intensivist who never makes mistakes), it is the five components and their interactions that determine if care is safe and of high quality. Second, if one changes any of these components, it will have impact on the other components and their interactions. This is illustrated through the routine practice of cannulation for extracorporeal membrane oxygenation (ECMO) in the PICU. Merely changing the environment from the PICU to the hospital parking lot would have dramatic implications for the people, their tasks, the tools, and the organization's culture and liability. A third implication of this model is that changes to one or more of the five components will inevitably impact their emergent properties of safety and quality. This is illustrated by the growing literature that suggests that safety technologies may actually cause errors and harm.[6-11] Thus for critical care providers, understanding the role of systems in the work done in an intensive care unit (ICU) is crucial to improving quality or reducing harm.

Additional characteristics of systems that are important to intensivists are their complex adaptive nature[12] and the concept of tight coupling.[13] A complex adaptive

system is one with several characteristics. First, complex adaptive systems have multiple similar agents that are autonomous entities that observe and act on their environment (such as PICU providers). More important, these multiple agents are adaptive, allowing for a high degree of resilience to system changes. The complex adaptive nature of the PICU is illustrated by sudden, unpredicted events such as codes, an unplanned extubation, or even multiple simultaneous admissions. In each of these scenarios, the future was unpredictable, the response was adaptive, and order is emergent rather than predetermined.

A tightly coupled system has events that must occur sequentially; it does not tolerate variation in supplies or inputs without creating delays and may tolerate failures less well than systems with slack designed into them. An example of tight coupling in the PICU is the common challenge of patient flow. An unplanned admission from the operating room (OR) requires a PICU bed postoperatively. The OR team is under pressure to transfer the patient to the PICU as soon as possible to free up the OR and prevent delays in the surgical schedule. However, the patient who could leave the PICU cannot be transferred because there is no floor bed. There are no floor beds because there is a delay in paperwork and the need for a parent to drive the floor patient home. In this process, failure at any step leads to delay, the steps allow for little variation in process, and the majority of steps must occur sequentially. These features of complex, tightly coupled systems are endemic in health care settings.

Quality Improvement and Value

Quality has been defined as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge."[14] This definition, which comes from the Institute of Medicine, draws from the work of Donabedian.[15] In his work, quality was defined in the context of structure, process, and outcomes. In other words, to measure quality, one should consider the structure or capacities of health care, the process or interactions between patients and care providers, and the outcomes or evidence of changes in a patient's health condition. Ideally, considerations of quality should incorporate all three components.

The Institute of Medicine has identified six essential domains for achieving health care quality.[16] These areas include safety, effectiveness, patient-centeredness, timeliness, efficiency, and equity. Based on these and Donabedian's components of quality, efforts to improve quality should consider improvement of process, structure, or outcome focused on one of the six areas identified by the Institute of Medicine. The six domains, their definitions, and PICU-relevant examples are displayed in Table 11.1.

A discussion of the definition of quality should include potential shifts in thinking. Of note, there is literature suggesting that beyond quality, the issue of value is important to health care. In this context, value is defined as a measure of quality per unit cost.[17] This can be illustrated by considering what automobile the reader drives. Whether an entry-level compact car or a loaded luxury vehicle, for each consumer there is some determination of both the quality of the vehicle and whether that quality is worth the cost. Although robust measures of quality and true costs remain elusive in health care, critical care providers could improve value to patients by

improving quality, reducing cost, or both.

Quality Improvement Methods

QI seeks to improve the quality of care. To improve care, one must first define the process of care that needs improvement. Ideally, a goal is set to define what is desired in terms of the outputs of the process. Then data are obtained to understand the process, and finally interventions are made with follow-up measurement to assess the change, positive or negative.[18]

Several important components are included in the previous paragraph. First, one must define and understand a specific process or system. This is critical to making improvement feasible. For example, a hospital may identify that its length of stay (LOS) for patients with diabetic ketoacidosis is prolonged compared with peer organizations. However, efforts to improve all the elements involved in the hospital course simultaneously likely will fail because of the magnitude of the efforts. Instead, by identifying the components included in the hospitalization and contributing to the LOS, it may be possible to focus on manageable segments of the care process and make incremental changes (Table 11.2).

A second important concept is understanding variation in the data and the value of data over time (see the section titled "Variation and Display of Data Over Time"). As data are understood, goals can be set and interventions made. Continuing data acquisition allows assessment of the impact of the interventions. The establishment of goals provides a target for interventions and a context for measuring data. To paraphrase a QI cliché, changing a process through an intervention is not the same as improving a process. Instead, measurement of data and comparison to set goals allow for assessment of improvement.

Ideally, these changes and reevaluations are done in an iterative manner. This method has been labeled as the "plan, do, study, act (PDSA) cycle."[18] The Institute for Healthcare Improvement (www.IHI.org) has advocated use of a PDSA method over a short period to create what it calls "rapid cycle improvement." With either model, changes often are introduced quickly and sometimes multiple changes are introduced simultaneously. This method has evoked pushback from some physicians because of an apparent lack of scientific and statistical rigor. From a QI standpoint, many improvements are achieved without the need to meet a given P value. Ironically, the resistance to QI methodology because of lack of statistical rigor is inconsistent with much clinical practice in the PICU. There does not exist a standard of care that every intervention performed in resuscitating a patient be accompanied by evaluation for statistical significance. In fact, resuscitations may involve multiple interventions (endotracheal intubation, chest compressions, administration of medications) in a rapidly sequential or simultaneous manner. With a successful resuscitation, an intensivist may be unable to identify which of numerous interventions was responsible for the improvement. Arguably, if improvement occurred, neither the patient nor the family necessarily cares which intervention resulted in the positive change. Such is the QI mindset. If a given intervention can be identified and causation established for a specific improvement, this information may be applied to different settings. However, the goal is improvement, and improvement without clear identification of the causative factor remains an improvement.

Variation and Display of Data Over Time

If an intensivist watches a physiologic monitor for any length of time, it is normal to view variability in heart rate and other vital signs. This reflects the dynamic nature of physiologic systems and processes. Similarly, health care processes vary within certain ranges under normal circumstances. Reacting to changes within normal variation may lead to interventions that increase variation rather than reduce it.[19] However, the range within which the variation is occurring may be outside the desired goal. Thus improvement may address the amount of variation associated with an existing system or fundamental redesign of the system.

Again, understanding the normal variation in a process is critical. The PICU provides physiologic illustrations of this concept. A patient who is doing reasonably well in the PICU has a normal range of heart rate variability, and loss of heart rate variability has been associated with increased risk of death in certain populations.[20] Similarly, a relatively well patient in the PICU who acutely develops either tachycardia or bradycardia merits evaluation for new or worsened pathology. In this case, the heart rate variation that normally occurs does so within certain parameters. This variation is called *common cause variation* in the QI literature. When the variation crosses either the upper parameter (tachycardia) or lower parameter (bradycardia), then something is amiss. The same holds true for processes and systems within health care. Variation that crosses certain thresholds or is an abnormal outlier is called *special cause variation.*

Plotting data over time allows for an understanding of this variation, normal or abnormal, in data. When data points (eg, length of stay) are placed on a chart with time (eg, in days) plotted on the ordinate, this is called a *run chart. Control charts,* or statistical process control charts, also plot data over time. However, control limits are added that help define the limits of normal variation. Control limits, first described by Walter Shewart in the 1920s, are calculated in a variety of statistical manners, in part depending on the type of control chart. The type and distribution of data determine the choice of control[21]; methods for choosing a control chart are beyond the scope of this chapter. At the most basic limit, control levels are set at three times the standard deviation of the data, around the line of central tendency.

In general, when data exist within the control limits, a process is said to be in control. Data that either extend beyond the control limits or demonstrate one of several patterns suggest either an unstable process or a process that is responding to a change. This change may be an intentional effort to alter a process or may represent the effect of an unknown cause. Returning to the heart rate analogy, a patient who becomes bradycardic from hypoxia would demonstrate deviation of the normal heart rate variation in response to the special cause (hypoxia). Correction of the hypoxia ideally returns the heart rate (process) to its normal range of variation. An example of a control chart is displayed in Fig. 11.1, which illustrates the rates of codes outside the ICU relative to the introduction of rapid response teams.

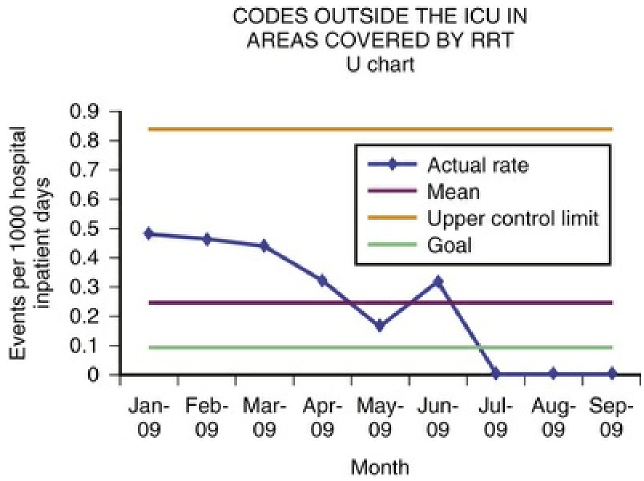

FIG. 11.1 Control chart demonstrating codes outside the pediatric intensive care unit in areas covered by a rapid response team (RRT).

Other Quality Improvement Tools

Interested readers are directed to one of the numerous QI primers available for a thorough discussion of tools used in QI. However, several of these tools bear at least some mention. A Pareto chart is simply a histogram used to identify the major contributors to a problem or variation. For example, if PICU length of stay (LOS) is of concern, it may be beneficial to identify which, if any, diagnosis categories contribute to the prolonged LOS. By plotting LOS in days on the abscissa against diagnosis on the ordinate, those diagnoses that contribute to the greatest portion of the length of hospitalization might be identified.

Root cause analysis (RCA) is another tool used to attempt to identify the root cause for an event or problem. In its simplest form, RCA is performed by asking the question “why?” five times. Often used in conjunction with a cause-and-effect or Ishikawa diagram, the process of root cause investigation seeks to identify what caused a failure in a process (safety related or quality related) by defining the contributing factors. From each of the five categorical branches, smaller branches are added that answer the question “why?” and in turn the same question of “why?” is asked again. The resultant diagram often is described as a fishbone, explaining the third name for this diagram: a fishbone diagram.

By asking “why?” repeatedly, the belief is that the root cause of a problem can be identified. This leads to three limitations of RCA. First, there is the great danger of introducing hindsight bias. The investigators' beliefs of what happened may lead them to identify only those things on the cause-and-effect diagram. A second, related limitation is that RCAs may restrict problem solving and brainstorming to only those factors that are known. Because one only knows what one knows and, similarly, one doesn't know what one doesn't know, there is the potential for missing important factors. Finally, the most important limitation of RCA as a tool is the suggestion that there is a single root cause. This is a dangerous belief. Usually there are multiple causes of events. To limit thinking to one or two causes oversimplifies the situation and may preclude meaningful improvement. The use of RCA should be tempered with the knowledge of these limitations and the potential for drawing incorrect conclusions. For an excellent and sobering discussion of the limitations of RCA,

readers are encouraged to read works by Nemeth, Wu, and Nicolini.[22-24]

Fundamentals of Patient Safety With an Introduction to Safety I and Safety II

Traditionally, patient safety is defined as freedom from preventable injury, an adaptation of the definition used by the Institute of Medicine.[2] This definition is in keeping with what is now known as Safety I, with an associated goal of minimizing the number of times when things go wrong. Safety I views the causes of things going wrong as human, organizational, and technical failures. Further, it presumes systems of care to be well understood, highly predictable and reliable—with the exception of the human element.[25,26] An alternative viewpoint is that safety is when things go right under a variety of circumstances. This Safety II approach understands that not only are people part of systems but safety primarily occurs from people adapting to suboptimal systems in the face of changing situations (Table 11.3).

TABLE 11.3

Contrasting Safety I and Safety II

Characteristics	Safety I	Safety II
Defined by:	Its opposite: failure	Its goal: success
Systems are:	Well designed, well understood	Poorly understood, dynamic
Procedures are:	Correct and complete	Incomplete, underspecified, and based on imagined concept of how work is done, not on how work is actually done
People:	Are flawed, prone to violations, and thus a liability Should behave as expected and trained	Adjust behavior and interpret procedures based on the context
Accidents come from:	Failures in human compliance, malfunctions, and variation in human behavior	Incomplete adaptation to situations
Safety management approach	Reactive, responding to events	Proactive, seeking to anticipate and prevent events

Adapted from Hollnagel E, Leonhardt J, Licu T, et al. From Safety I to Safety II: a white paper, 2013. Available at www.eurocontrol.int; Hollnagel E. A tale of two safeties. Nuclear Safety and Simulation, 2013;4:1-9; and Robert Wears (personal communication).

Safety I can be compared to quality assurance (QA) in health care. QA was the predecessor to QI and largely focused on assuring compliance with policies and reactively finding fault when something went wrong.[27] However, although flawed, not all aspects of Safety I are bad. For instance, variation from following the central venous catheter insertion bundle is an example of a nonvalue added variation that largely poses risk without benefit.

Errors, Injuries, Systems, Hazards, and Risks

A central goal of all health care is to provide care without causing harm. Unfortunately, the identified harm in health care is often incorrectly attributed to a problem with errors, instead of understanding that both errors and harm are the result of poorly designed systems of care that either promote errors or allow harm to occur in the face of errors. This is manifested through such statements as “We wouldn't have this safety problem if we could stop people from making so many

errors." This, in turn, suggests that to achieve safety, we simply need to urge people to follow policies and be careful. However, people make errors; as long as there are people in PICUs, there will be errors. To that end, there are numerous safety improvement efforts that focus on people that can be seen by the following solutions: warning labels, signs and posters exhorting staff to "be careful" and to "do this" or "do not do that," repeated educational campaigns, and reliance on policies and procedures. None of these activities is bad per se, and in fact they can be part of an effective safety effort. However, they are not sufficient to provide safety. In each of those "solutions," the goal is to error-proof the people, despite the inherent property of people to err. No amount of rules, education, or warnings will prevent errors from occurring.

In contrast, the science of human factors engineering (HFE) supports the belief that efforts to improve patient safety that depend on requiring people to be infallible are misguided, wasteful, and potentially harmful. The previous section on systems thinking clearly identified patient safety and quality as emergent properties of systems. Not surprisingly, there is research that demonstrates that errors often are caused by poorly designed systems, or design-induced errors.[28] Therefore if an error occurs, one should not ask "why did the person make the mistake" but rather "what caused the mistake to occur?"

A clinical example that is relevant to PICU care is the restriction of the availability of high-risk medications. Sources of medication errors include the storage of look-alike vials or medications of the same name but differing concentrations in the same area for use in the PICU. In this case, the look-alike medications represent hazards, which may or may not lead to errors and injuries. An incorrect look-alike medication can be given in error, potentially resulting in harm. A safety program focused on people would solve this problem through educating staff to pay more attention to look-alike vials and to make the labels on the medications appear more distinct. In contrast, an HFE or system-based approach would involve elimination of the hazard by removing the high-risk medications to another area, making it impossible to confuse medications or concentrations. In others words, by redesigning the systems for medication storage and access, the opportunity for error (and harm) decreases or even vanishes. Central to this solution is the characteristic of using system redesign to reduce the risk of errors and harm. Consistent with epidemiologic and public health models that attempt to identify, understand, and reduce risk factors for disease or injury, the risk-reduction approach described here is a standard HFE and safety science approach.[29-31]

Improvement in the Pediatric Intensive Care Unit

The thought of improving safety in the PICU is daunting. The number and complexity of care processes seem overwhelming, and it is reasonable to wonder how to even begin. Building on the concepts of systems and risk reduction, a simple approach to improving patient safety in the PICU involves three steps: risk identification, risk analysis, and risk reduction.[32]

The process of risk identification is relatively straightforward. Drawing on reported events, chart reviews, concerns identified by staff, patients, and families, as well as issues identified in other units in a hospital, one can compile a list of potential risks that may be relevant to the patients cared for in the PICU. Of note,

both errors and injuries inform the identification of risks. However, rather than focusing exclusively on trying to reconstruct prior events, the idea is to use past events to guide proactive improvement efforts to prevent future risks.

As the list of identified potential risks is generated, the next step is to systematically analyze the risks. This analysis involves three major steps. First, ask: "Is our PICU at risk for this happening?" If the identified risk was related to a published report of ECMO pump failure and ECMO is not performed in your PICU, then you can safely conclude that this risk does not apply. In contrast, if your PICU does perform ECMO, then the second step involves gathering more information to inform the risk assessment. This step might involve understanding what brand or type of pump was failing and whether this pump is in your center. Finally, after all available data are gathered (or perhaps new data are collected), the final step in risk analysis is to provide clinical interpretation by clinical experts familiar with the process. In the case of the ECMO pump scenario, a group of surgeons, intensivists, nurses, and perfusionists would weigh available data to determine the extent of risk for their PICU population.

The last step of improving safety would be performing risk reduction, which would involve pulling together a team to brainstorm improvements and the potential unintended consequences of each potential improvement. The latter portion of this step is critical. A simple but potentially hazardous solution to the ECMO scenario would be electing to cease all new ECMO support. Although this solution would surely prevent adverse events from ECMO pump failure, it might also result in preventable harm to patients who could be saved by ECMO. Similar to the step of risk analysis, risk reduction requires people knowledgeable about the processes to help guide improvements and prevent introducing unintended new risks.

Understandably, not every risk identified in the PICU is amenable to reduction by the PICU team alone. For risks that cross multiple units or may require significant resource investment, the identified and analyzed risks should be communicated to hospital leaders who then can weigh these risks with all others identified in the organization. However, this proactive and evidence-based approach can provide a standard framework for safety improvement. Additionally, this risk-based safety improvement approach lends itself readily to risk-based safety metrics.[75-77]

Culture

As attention shifts from individuals to systems, inevitably the issue of accountability is raised. Commonly expressed concerns center on whether focusing on systems rather than individuals somehow absolves health care providers from responsibility. In part, this concern arises from a well-intended (but misguided) effort to move from a punitive culture in health care to a blame-free environment. The intention was not to create systems lacking individual accountability but to avoid blaming individuals for situations beyond their control or that resulted from human error to which anyone would be vulnerable.

One solution that represents a system focus has been described as a *just culture.*[33] Under this model, systems problems and human error are considered. The model promotes efforts to learn from errors without punishing individuals involved. Systems problems that create situations in which individuals are "set up" to make

errors also are treated as learning opportunities. When individuals violate policies, often because of normalization of deviance, the response again is not punitive but instead focused on making it easier to do the right thing. In the PICU, this can be seen when workload constraints make performing required double checks on pump programming unrealistic. Staff members may fail to perform double checks daily without event, and no action is taken to stop the behavior. However, when a neglected double check leads to an error or harm, the traditional mindset is to punish the involved parties, despite a systematic acceptance of this behavior. In a just culture model, rather than punish the individual, efforts are made to again make it easier or more desirable to do the right thing.

Systems thinking and a just culture are consistent with punishment. This may occur in the face of willful or reckless behaviors that place patients at risk. If a physician provides patient care while intoxicated, this is an example of reckless behavior that would be unacceptable in a just culture. When behaviors show a pattern of violations that individually may not represent reckless behavior but collectively demonstrate a high-risk pattern, the just culture model proposes two considerations.[34] First, the person may work in a high-risk situation where such patterns are inevitable. Alternatively, the person involved may have individual characteristics, such as marital stress or deteriorating physical abilities, which would require removing the person from that situation in a nonpunitive manner. It should be noted that, on rare occasions, individuals may be viewed as out of control because of mental health problems, substance abuse, or even patterns of behavior. As mentioned previously, a just culture would require prompt intervention to help or remove these individuals to prevent harm to patients and other providers.

Importantly, the SPS adoption of Healthcare Performance Improvement (HPI)'s framework for serious safety events (SSEs), though presented along with a just culture framework, promotes blaming people. The HPI (and thus SPS) framework for prioritizing safety events focuses on "deviations from generally accepted practice standards."[35] According to HPI, these are either due to human error or to equipment failure. Beyond ignoring all science related to socio-technical systems, the HPI framework also shows a lack of understanding of the ubiquitous nature of deviations and violations by providers to compensate for otherwise unworkable systems of care delivery.[36-38,75-77] As a result, the patient safety efforts have largely shifted to a reactive, people-focused version of "whack a mole," chasing the last safety event while searching for the root cause to blame.

Teams and Teamwork

The need for improved teamwork is a recurring theme in patient safety. This is certainly true in the PICU environment. However, there are important differences in how critical care physicians and nurses perceive what is meant by teamwork and how well their teams perform.[39] One conclusion by the authors is that these differences might be due to training, gender, or role-related culture. Another potential explanation may be a poor understanding of the sciences of teams and team performance.[40-47]

In PICUs, there are a variety of teams. There is the patient's care team comprising the nurses, respiratory therapists, pharmacists, attending physicians, and perhaps trainees such as residents and fellows. There are also the within-discipline clinical

teams, such as the nursing or physician team that cares for a given patient over shifts, days, and weeks. A nurse and his or her nursing assistant might also be a team, as might all of the nurses on a given shift in a given ICU. However, despite that fact that we might call each of these *teams,* that does not mean that they identify themselves or perform as teams.

Teams are "two or more individuals with specialized roles and responsibilities who must interact dynamically and interdependently and are organized hierarchically to achieve common goals and objectives."[46] But more than that, according to HFE evidence, high-performing teams are those that have been trained to have, and have demonstrated proficiency in, specialized knowledge, skills, and attitudes that support teamwork.[33] For example, in high-performing teams, all team members have the following knowledge: They share the same mental model of what needs to get done, they all know the team mission, and they all know each others' roles and expectations. Similarly, in high-performing teams all team members have been trained and have demonstrated proficiency in the following skills: backup behavior, team leadership, conflict resolution, and closed-loop communication, among others. However, few health care organizations train their staff to have that knowledge or those skills. Until that happens, HFE research suggests that there will not be high-functioning teams in health care (including PICUs).[47]

Technology

PICUs are full of technology. Not surprisingly, there is a perception that additional technologies may enhance safety. This perception exists despite the fact that *fallible humans* design the technologies used to prevent human error. Specific technologies attributed with improving safety include electronic health records, clinical decision support, computer provider order entry (CPOE), bar-coded medication administration, and "smart" infusion pumps. These technologies have been linked to a reduction in errors, even though little evidence exists that they reduce harm to patients. There is also evidence that these technologies can introduce new types of errors, violations, and harm.[6-11,48-54]

That technologies intended to improve safety may create added errors, rule violations, and risks may seem counterintuitive. However, the systems model described previously helps explain this seeming paradox. For instance, CPOE does not exist in a vacuum within the ICU. Instead, people (physicians, nurses, pharmacists) must use the CPOE system to perform tasks (ordering, modifying, and managing medications) within a busy and often distracting ICU environment. Independent of whether the CPOE system works as intended, the interactions among technology and people, tasks and environment, not to mention how the technology was implemented and supported, will ultimately determine whether the CPOE improves or sometimes worsens medication safety.[55] Health information technologies intended to improve safety may have usability problems[56-61] that increase the likelihood of user errors, provide misleading feedback, lead to high rates of false alarms, or cause difficulties interpreting data. Examples of usability problems include CPOE systems that preselect a patient, increasing the likelihood of entering orders on the incorrect patient, and defibrillators that have unclear displays resulting in failed attempts of patient cardioversion. If such usability problems exist, they can lead to the previously mentioned design-induced errors.

The issue of alarm and alert fatigue (the latter from electronic health records [EHR]) is an increasingly problematic issue. Both stem from fundamental problems with how monitors, devices, and EHRs are designed. The result is whole-scale desensitization of providers because of the poor signal-to-noise ratio. Perhaps what is most worrisome about this issue is that there exists no literature on resensitizing providers.[62-64]

As with team training, there is a rich body of non–health care literature and a growing body of health care–specific literature that can guide the design, selection, and implementation of technologies to yield the best results.[65-68] Without leveraging this knowledge, PICU providers risk the unintended but foreseeable consequences of suboptimal technology adoption and potential harm to their patients.

Patient Safety in the Pediatric Intensive Care Unit: Past, Present, and Future

The body of health care safety science has grown dramatically since the previous edition of this text. Now, patient safety is the subject of its own textbooks, with numerous national and international meetings devoted to expanding knowledge and improving solutions (Table 11.4). With this in mind, it is impossible to provide a complete discussion of all topics for the PICU audience. It is important to know that there are many important topics worthy of additional consideration. These include fatigue and performance in the PICU, the potential for simulation, and the importance of leadership and the culture of safety in the PICU.

TABLE 11.4

Sampling of Major Patient Safety Meetings and References

Meeting or Text Title	Annotation
National Patient Safety Foundation Annual Patient Safety Congress	Annual national conference focused on patient safety improvement
Agency for Research and Quality Annual Conference	Annual national conference focused on the science of patient safety
Institute for Healthcare Improvement's Annual National Forum on Quality Improvement in Health Care	Annual national meeting focused on quality with some emphasis on safety
National Initiative for Child Healthcare Quality's Annual Forum on Improving Children's Healthcare and Childhood Obesity Congress	Annual national meeting focused on pediatric quality with limited emphasis on safety
To Err Is Human: Building a Safer Health System	Seminal publication addressing the patient safety problem in the United States
Handbook of Human Factors and Ergonomics in Health Care and Patient Safety	Authoritative text providing the basic science of patient safety
Internal Bleeding: The Truth Behind America's Terrifying Epidemic of Medical Mistakes	Despite sensational title, an excellent introduction to patient safety issues

There is an evolution in the approach to patient safety within a clinical environment, including the PICU. The most basic approach that still exists in health care is one of denial (ie, the belief that a PICU has no safety issues). However, in the absence of concrete evidence that harm such as CA-BSIs or decubitus ulcers do not occur in that unit, this approach resembles that of the Flat Earth Society: unfounded disbelief.

Beyond denial is the reactive approach, characterized by error counting, blame finding, and people-based solutions. One example of organizational implementation of a reactive approach is the previously discussed HPI framework adopted by SPS.[35]

Unfortunately, this approach may be well intended but harmful because of the impact on care providers and the culture of safety. Next is a proactive approach in which PICU teams seek to identify, understand, and reduce risks in their environment. However, nothing about this approach assures that variation will not undermine safety improvement efforts.

The desire to eliminate unwanted and harmful variation is central to the standardization-based approach to safety. In these aspiring "high-reliability organizations," there is a focus on standardization of processes in the care environment. For processes such as preparing and dispensing a medication, handoff communications, or placing a central venous catheter, standardization will reduce unwanted variation and potentially reduce waste while improving quality and safety. At the same time, the practice of standardization can be overused. Standardizing the ordering, dispensing, and administration processes of aminoglycosides in septic PICU patients would be beneficial; standardizing to a single dose of aminoglycosides regardless of patient age, weight, or renal function would be potentially dangerous.

If standardization of a process will support the needs of ICU providers in all or nearly all cases, HFE supports its use, allowing exceptions for the few cases where a standard process does not apply. If, on the other hand, standardization will only support the needs of the providers some of the time, then standardization may be problematic. After all, if a standardized process does not fit many typical situations, then standardizing will simply create more "violators."

The goal of safety programs both in and out of the PICU is resilience. "Resilience is the ability of systems to mount a robust response to unforeseen, unpredicted, and unexpected demands and to resume or even continue normal operations."[69] Any PICU faced with a mass casualty or even simultaneous cardiac arrests in patients understands the challenge of unanticipated demands on the system of care delivery. What is less clear is whether the PICU team can rise to meet these demands while still providing care to the other patients in the PICU. Safety science has revealed that it is the people in the complex systems that provide resilience or the ability of the system to function safely despite the inherent complexity and the risks.[70,71] Thus when PICUs are provided resources and designed such that they can meet these demands while providing care to the other patients and assure safe and high-quality outcomes, then the goal of resilience is met.

Conclusions

The issues of patient safety and quality have proved to be more than a fad. Patients, their families, payers, regulatory bodies, and a growing number of health care professionals are all focusing on these issues. As is true with any complex system, there are no easy answers to improvement, and improvements targeted at fixing people are destined to fail. Instead, by learning and applying quality and safety science, there is the opportunity to enhance the historically good outcomes achieved in the PICU.

CHAPTER 12

Information Technology in Critical Care

L. Nelson Sanchez-Pinto, Steven Pon, Barry Markovitz

PEARLS

- Health care organizations around the world are adopting digital infrastructures, opening the door to a data-driven and evidenced-based transformation of the way we take care of our patients. However, the road ahead is long and not without hurdles.
- Physicians must learn about the evolving information technologies in health care to develop realistic expectations, maximize their benefit, ensure patient safety, and avoid pitfalls.
- In most institutions, administrators and nurses drive the advancement of various information technologies. Physicians, especially intensivists, must become involved in the selection and development of these technologies if their needs and concerns are to be adequately addressed.
- Organizations and clinicians must ensure the security and confidentiality of personally identifiable protected health information. They must understand the legislated privacy rules and safeguard the security and confidentiality of patient data.
- As each incremental phase of implementation of an electronic health record is approached, the focus should be on overcoming specific barriers to care rather than on the nebulous goal of "creating a paperless process."
- Health care organizations that take full advantage of their digital infrastructures and data assets in an organized, systematic, and attentive manner will stand to benefit the most in coming years.

Medicine is an information service. From the bits of data that stream out of the patients' monitors and the stories the patients recount to the signs and symptoms identified by clinicians and the diagnoses they formulate, medical information is wielded to protect life and shepherd death. Compassion, judgment, and technical skill may distinguish excellence in the discipline, but information defines the science of medicine.

Health care systems around the world are undergoing a digital revolution, and the adoption of electronic health records (EHRs) is just one of the early steps. This digitalization, along with the extraordinary advances in the biomedical sciences, is contributing to the remarkable expansion of medical information. This deluge of "big data" threatens to drown even the most conscientious clinician, who devotes every waking hour of every day to collecting, cataloguing, assimilating, and applying the information that will help his or her patients. Fortunately, advances in health information technology (IT) can also facilitate this task. Health IT gives us immediate access to vast knowledge and decision support while streamlining the tedious chores of searching and collating information. It has changed the way we practice medicine, and it continues to evolve every day.

Demonstrations of the potential of health IT typically inspire awe and admiration. However, when the technology migrates from demonstration to actual use, awe and admiration sometimes give way to disappointment. The novel features that users think they need are either impossible to achieve or require significant reengineering of the original product. Health IT is continually improving, but understanding its limitations is as important as envisioning its promise.

Health IT has a long road ahead of it to achieve its full potential. Physicians, especially intensivists, should help chart that road and keep the focus on the most important of our tasks: improve the care we provide to our patients.

Digital Infrastructure in Health Care

Great effort has been devoted in the past decade to digitalizing health care in the United States and around the world. The US federal government has been especially active in this purpose by incentivizing the adoption of EHRs and accelerating the data utility across the country.[1] One of the major advantages of a digitalized health care system is the potential to analyze the electronic information of health care transactions, both clinical and nonclinical, in order to learn what practices improve care and reduce costs. This so-called "learning health system" has been hailed as the way to continuously improve health care.[2,3] It is estimated that, if the US health care system were to make use of its electronic data in an effective way, it could save up to $300 billion per year.[4]

HITECH Act and Meaningful Use of EHRs

The Health Information Technology for Economic and Clinical Health (HITECH) Act was enacted under the Title XIII of the American Recovery and Reinvestment Act of 2009 and carries a commitment of up to $27 billion to improve the US health information technology infrastructure.[1] The HITECH Act outlined plans to encourage implementation and meaningful use of EHRs through the Centers for Medicare & Medicaid Services (CMS) EHR Incentive program. This program has evolved to include three stages, each with its own goals and priorities and with different incentive dollars depending on the year of adoption of each stage by hospitals and providers.

The EHR meaningful use criteria stages are:

- *Stage 1* (which began in 2011), which focuses on electronically capturing health information in a standardized format, tracking key clinical conditions, and sharing

clinical quality measures;

- *Stage 2* (2014), which focuses on rigorous health information exchange, e-prescribing, and increased emphasis on patient-controlled data; and
- *Stage 3* (2016), which focuses on improving quality, safety, and efficiency in order to improve health outcomes.

In addition to the CMS Medicare and Medicaid EHR Incentive program, the HITECH Act created programs to regionally support the implementation of EHRs, support state-level health information exchange (HIE) projects, create health IT workforce training programs, fund health IT research through the strategic health information technology advanced research projects (SHARP), develop interoperability standards and specifications, and create the Nationwide Health Information Network (NHIN)—a common national platform for health information exchange (Fig. 12.1).[5]

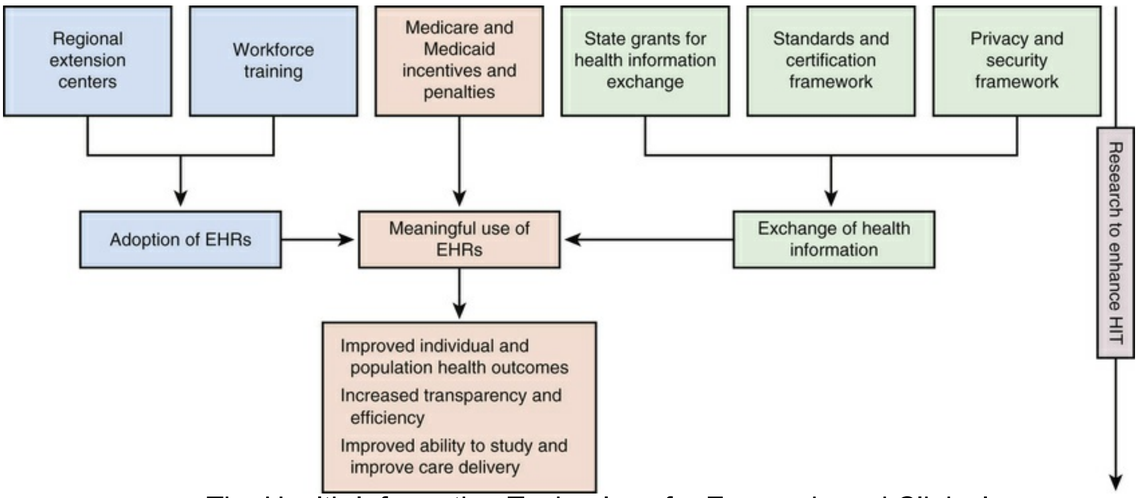

FIG. 12.1 The Health Information Technology for Economic and Clinical Health Act's framework for meaningful use of electronic health records. *EHR*, elecronic health record; HIT, health information technology. (From Blumenthal D. Launching HITECH. N Engl J Med. 2010;362:382-385.)

Learning Health System

The Institute of Medicine, sponsored by the US Office of the National Coordinator for Health Information Technology, published a report in 2011 that explored strategies to accelerate the implementation of a digital infrastructure in health care and the development of a learning health system.[2] They defined the learning health system as a system "designed to generate and apply best evidence for collaborative health choices of each patient and provider; to drive the process of discovery as a natural outgrowth of patient care; and to ensure innovation, quality, safety, and value in health care." Information technology is the functional engine of such a system, and hence the development of the digital infrastructure is a natural prerequisite (Fig. 12.2).

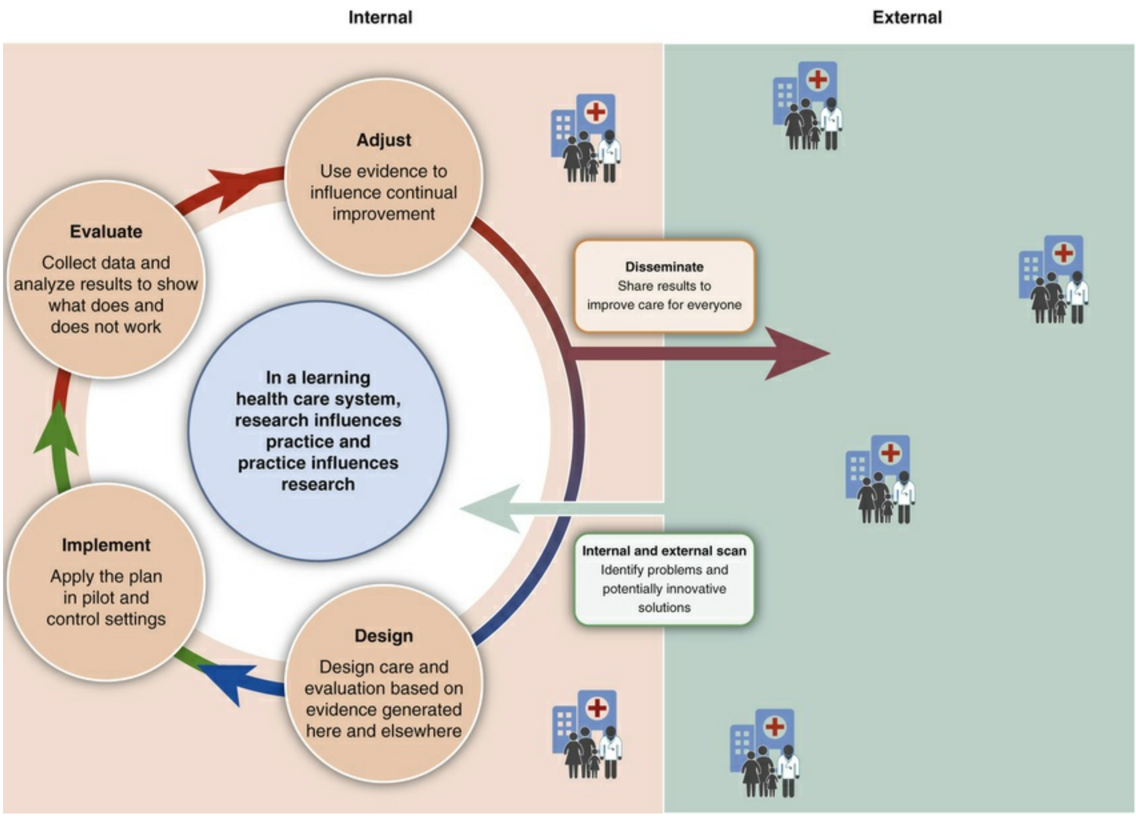

FIG. 12.2 Phases of the learning health system, as proposed by the Group Health Cooperative, Seattle, WA. (From Greene SM, Reid RJ, Larson EB. Implementing the learning health system: from concept to action. Ann Intern Med. 2012;157:207-210.)

The need for a learning health system in the United States stems from the paradox in which the health system finds itself. The rapid growth of molecular diagnostics, genetics, proteomics, imaging, and therapeutics is overwhelming clinicians and patients who have to sift through more and more information with each decision. At the same time, we lack of evidence of which approaches are the most beneficial, cost-efficient, and safe. The impact of all this is compounded by the fact that health care costs continue to rise, exhausting the purchasing power of consumers and reducing the competitiveness edge of US employers, yet patient outcomes are less than optimal when compared with other large health care systems around the world.

The Institute of Medicine expanded this topic in 2012 with the report *Best Care at Lower Cost* in which it makes 10 recommendations to radically improve the US health care system.[3] The first three recommendations are in direct relationship with the learning health system and the use of clinical decision support (CDS):

- *Recommendation #1: The Digital Infrastructure*. Improve the capacity to capture clinical, care delivery process, and financial data for better care, system improvement, and generation of new knowledge.
- *Recommendation #2: The Data Utility*. Streamline and revise research regulations to improve care, promote capture of clinical data, and generate knowledge.
- *Recommendation #3: Clinical Decision Support*. Accelerate integration of best clinical knowledge into care decisions. Decision support tools and knowledge management systems should be routine features of health care delivery to ensure that decisions made by clinicians and patients are informed by current best practice.

The report also recommends that health care organizations invest in advanced health information technology and CDS systems and encourages the use of these tools through incentives. Furthermore, the report recommends that public and private payers promote the adoption of these systems by structuring payments and contracting policies that reward effective and evidence-based care practices.

Clinical Informatics Subspecialty in the United States

The field of biomedical and health informatics has grown significantly in recent years due to the increasing role of information technology in health care and higher demand for a skilled workforce that can bridge the science of information with the reality of clinical care.[6] Clinical informatics is a subspecialty of biomedical and health informatics that focuses on analyzing, designing, implementing, and evaluating information systems that improve care, reduce cost, and/or enhance the experience of health care consumers. There are a number of graduate-level courses, master's degrees, fellowships, and doctorate programs designed to train health care professionals in the field of clinical informatics. In 2011, the American Board of Medical Specialties (ABMS) announced the creation of a physician certificate in clinical informatics and the first examination was offered in October 2013 by the American Board of Preventive Medicine. To be eligible for the examination, candidates must be certified by any of the 24 Member Boards of the ABMS (including the American Board of Pediatrics), hold a current medical license, and either satisfy the practice pathway requirements (at least 3 years of clinical informatics practice comprising 25% or more of a full-time equivalent) or have completed a 24-month clinical informatics fellowship. Starting in 2018, only graduates of an Accreditation Council of Graduate Medical Education–approved clinical informatics fellowship will be eligible for certification.[7]

Electronic Health Record

The EHR is defined as a comprehensive database of personal, health-related information that is accessed and updated across a health care network.[8] Its potential and real benefits include the following:

- Improved quality of care through more timely, more complete, and better-organized information delivery to the health care provider, with decision support and clinical pathways.
- Cost savings through elimination of duplicate testing, shorter lengths of stay, and more efficient data collection and review.
- Higher productivity by structuring patient care tasks to improve continuity of care and reduce practice variation by facilitating the creation of more consistent and more comprehensive content and by making the medical records more readily accessible to more users simultaneously.
- Facilitation of research, education, quality improvement, outcomes assessment, and strategic planning.

The three principal functions of such a database, like any database, are data acquisition, data access, and data storage.

Data Acquisition

The complete EHR acquires data from a variety of sources, including hospital registration, nursing and physician input, laboratory services, radiology and other test interpretations, therapist and nutrition services, monitoring devices, and physicians' orders. The most important system that feeds the database is the "enterprise-wide master patient index," which ensures that each patient is identified properly and uniquely. All other systems must have the correct identifier in order to deliver their data to the correct patient record. A multimedia database can include images such as radiographs, electrocardiograms, fetal monitoring, sonography, magnetic resonance images, computerized tomograms, and even paper-based documents such as consent forms, living wills, questionnaires, and, sometimes, handwritten notes and hand-drawn diagrams. Data acquisition is organized in a manner that minimizes duplicative effort and maximizes data consistency.

One of the significant challenges to any implementation of an EHR is engineering the various interfaces between it and the host of systems that feeds it data. Some of the feeder systems, such as laboratory services, have their own established validation protocols that are applied before transmission to the EHR.

Data originating from bedside devices such as cardiopulmonary monitors, pulse oximeters, ventilators, and intravenous infusion pumps represent critical elements of the patient care record. Manual capture and entry of these data into the EHR by nurses and other health care practitioners are associated with inefficiency and transcription errors. Technology is currently available to connect devices to the EHR through bedside medical device interfaces (BMDIs). BMDI allows properly formatted data from a medical device to flow into and update the patient's EHR.

One of the challenges in BMDI relates to the diversity of medical devices and EHRs, which makes it impractical for most vendors to directly connect. Often, biomedical device integration systems are required to extract, read, interpret, and forward data to the EHR in order for it to be useful. Basic physiologic data including heart rate, blood pressure, and respiratory rate are generally the first to be targeted for EHR integration. Other monitoring data that can be integrated with the EHR include temperature, pulse oximetry, end-tidal CO_2, and cardiac output measurements. Other devices that can be connected via BMDI include intravenous infusion pumps, ventilators, dialysis, hemofiltration systems, cerebral oxygenation monitors, and extracorporeal membrane oxygenation systems.

One of the clear benefits associated with BMDI is the improved efficiency associated with not having to manually retrieve and record the data. The increased efficiency therefore allows the nurse to spend more time at the patient's bedside or in other important activities. Though this time saving is minimal for any one piece of patient data, when the aggregated data for each patient and for the entire facility are considered, the opportunity for cost saving likely exceeds the cost of the initial investment. Another potential benefit is improved completeness and accuracy of the data in the EHR. BMDI increases data-sampling frequency possibilities, which is particularly important in a dynamic patient situation where data may be changing rapidly. Providers may request higher data sampling frequencies without impacting the need for additional patient care resources. In addition, reading and manually recording data into an EHR are often associated with transcription errors, the likelihood of which is reduced with BMDI. Having said that, inaccurate data can also

be sampled from the bedside monitors, such as when an electrocardiographic lead comes loose from the patient, and if this is not corrected by bedside providers, erroneous data can be introduced into the EHR.

Considering that a data element passes from one of several feeder systems through different computers, with possible transformations of that data element along the way, and considering the possibilities of lost transmissions, computer down-times, and network interruptions, consistent error-free data feeding would seem almost impossible. In a high-volume environment, a centralized interface engine that routes and converts transaction messages from disparate feeder systems, such as an enterprise service bus,[9] can solve many of the interface issues efficiently and in a timely fashion, with the added value of being able to perform streaming analytics and complex event detection using these electronic messages.[10]

The capture of textual information, such as progress notes, nursing assessments, or even radiology reports, presents particular challenges for several reasons. For the most part, text is entered via a keyboard hard-wired to the system but may be through voice or handwriting recognition or via handheld and wireless devices. Text entry with menu systems feeding structured and unstructured forms has been met with some success. Although these solutions do not have the same expressivity of free text, they lend themselves to the capture of text as structured data. Collecting structured data facilitates future analysis, but despite this significant advantage over collecting free text, it tends to be rigid, can make documenting the unusual impossible, generally requires more time to collect, and may be a significant source of frustration for the clinician. Another strategy is to allow free text entries but to apply natural language processing (NLP) to extract data from it for analysis. Even with the significant promise that NLP analytics represents in other care settings, one of the unique characteristics of the critical care environment is the abundance of structured data (vital signs, fluid inputs and outputs, medications administered, etc.) that remain underanalyzed.[11]

Data Access

The EHR serves as the focal point for most health care professionals. It might be accessed at inpatient sites but also in emergency departments, nursing facilities, continuing care centers, physician offices, clinics, laboratory facilities, treatment centers, and, in the case of home health services, the patient's home. An ideal EHR should be available when and where it is needed. However, databases with sensitive information must be controlled to prevent unauthorized use or alteration. These systems must satisfy five requirements:

1. Access control: Only authorized persons are allowed access for authorized uses.

2. Authentication: Some confirmation that a person granted access is, in fact, who he or she purports to be.

3. Confidentiality: No unauthorized disclosure of information is allowed.

4. Integrity: Information content is unalterable except under authorized circumstances.

5. Attribution/nonrepudiation: Actions taken (access, data entry, and data modification) are reliably traceable.

The interface through which most health care providers interact with the EHR should be user-friendly and intuitive. Most clinicians have little time or patience to sit through tedious training sessions, and, once trained, few clinicians will recall more than a minimum required to complete their immediate, routine tasks.

The system should be capable of providing a full, seamless view of the patient over time and across points of care. Views should be configurable so that a given user's information needs and workflow can be accommodated. Both detailed and summary views that juxtapose relevant data allow the clinician to acquire the information required to optimize expedient decision making. Displays should be configured to highlight key information while suppressing clutter but making all pertinent data readily accessible. Dynamic linkages should exist between the electronic health record and supporting functions such as expert systems, clinical pathways, protocols, policies, reference material, and the medical literature.

Response times must be sufficiently speedy, and workstations should be conveniently accessible to the point of care. Mobile connections are a bonus. Access to patient data via wireless connections with portable devices is an attractive alternative for users but must overcome usability and security hurdles before it can be fully implemented.

The patient database also supports many areas of research, education, decision support, and external reporting. Thus data in aggregate can be accessed by administration, finance, quality assurance, and research areas.

Data Storage

Multimedia data of the comprehensive EHR are stored on media that allow for long-term storage while allowing searches and rapid retrieval of enormous volumes of data. The database must be updated in a way that ensures it is current, complete, and consistent. Data, once entered, should be modifiable only in accordance with strict rules that ensure data integrity.

The architecture of the database can be centralized or distributed, replicated or not. A centralized database is stored at a single site, whereas a distributed database is a single logical database with segments that are spread across multiple locations connected by a network. A replicated database has the advantage over a nonreplicated database by having at least one copy of all records in case the primary copy is inaccessible because of computer or network failure. The challenge of replication is maintaining consistency among all the copies, which requires, in turn, timely, automatic synchronization of the original database and its replicas. More and more health care organizations are moving their EHR data to cloud-based computing systems as the federal regulatory, security, and privacy issues resolve.[12]

Once stored, the data should have a time stamp. Although data can be modified, both the original and revised versions should be maintained with appropriate time stamping. Appropriate safeguards must ensure database integrity so that its pieces do not lose their links and the data are not subject to unauthorized modification. Supplanting the paper record with the EHR as the official medical record requires thoughtful consideration of the limitations of paper copies to reflect accurately the

electronic record. Sanctioned hard copies of the patient record will be necessary for sharing with other health care institutions or with the legal system.

Whereas a clinical data repository is a database optimized to retrieve data on individual patients, a clinical data warehouse (CDW) is a database designed to support data analysis across individuals. This function can be distinguished from a simple archival function. The CDW structure is designed to support a variety of analyses, including elaborate queries on large amounts of data. The data are generally static and updated intermittently in batches rather than continuously.

Hospitals can use CDWs to perform financial analyses or quality assessments. With decision support tools, they can be useful in negotiating managed care contracts or distributing resources to clinical or ancillary services. Subsets of a CDW that are structured to support a single department or function are "data marts." These subsets are designed to perform periodic analyses or to produce standard reports run repeatedly, such as monthly financial statements or quality measures. Data mining applications can sift through mountains of data in the CDW and run complex algorithms to find obscure patterns (see section on Health Analytics).

Limitations and Pitfalls

Information technology in the form of an EHR promises improved patient care.[13,14] Potential benefits of information technology include providing rapid access to integrated clinical data and extant medical knowledge, eliminating illegibility, improving communication, and issuing applicable reminders and checks for appropriate medical actions.

A number of studies show that clinical information systems can provide various benefits, including increasing adherence to guidelines and decreasing medication errors.[15] However, any benefit may be outweighed by new problems introduced by the systems themselves. In effect, one set of problems may be traded for another.

The medical information space is vastly more complicated than it seems at first. EHR software programs are enormously complex, are built by large teams of programmers with input by numerous clinicians, demand high-speed processors and high-bandwidth networks, and rely on often fragile interfaces with other hospital systems. Implementation currently requires tremendous effort by both clinicians and technical specialists to configure these systems according to the specific needs of an institution and in ways that will enhance care rather than impede it. An often unappreciated complicating factor is that the technology does not simply replace paper; it also reengineers care—deliberately or not.

Errors can and do occur in programming or configuration. Many programming deficiencies can be detected and corrected with thorough testing, preferably in a development environment that does not affect real patients; however, some of these problems will only become apparent under unique circumstances that are presented by patient care. Indefatigable vigilance for these errors is essential.

Numerous other unintended consequences result from implementing an EHR, including the creation of new kinds of errors, an increase in work for clinicians, an untoward alteration of workflow and change in communication patterns, an increase in system demands, a persistence of paper use, and the fostering of potential overdependence on the technology.[16] Examples of unintended consequences are the "illusion of communication," where the user of the EHR is under the illusion that

entering information in the system is enough to communicate to the appropriate person who needs to act on that information, and juxtaposition errors, where a user might click on the adjacent name in a list and inadvertently enter the wrong information.

The benefit of legibility in electronically written notes can be outweighed by novel problems. Overuse of copy-paste functions can result in repetitive, monotonous, and loquacious notes punctuated by the sin of propagating erroneous text verbatim. Automatic transcription of data such as laboratory results or vital signs often bypasses cognition, something that is much less likely when data are transcribed by hand.

Documentation in a structured format rather than as free text can enhance completeness and facilitate later data retrieval; however, it can also increase work by forcing the clinician to find ways to fit round pegs into square holes. Similarly, rigidly structured order input can force clinicians to waste time trying different ways to order nonstandard tests or therapies.

Clinical alerts can help clinicians make decisions (eg, when penicillin is mistakenly ordered for an allergic patient), but persistent interruptions of work by alerts can increase the cognitive load of the clinician, who must decipher their meaning and assess the risk in each specific circumstance. The frequency of these alerts can become intolerable when they are not delivered to the right clinician, with the right information, and at the right time and place, leading to the so-called "alert fatigue" phenomenon.[17] When these alerts become too frequent and too predictable, clinicians often adapt by dismissing them automatically, which both diminishes the alert effectiveness and may ultimately harm the patient.[18]

Many care providers blame clinical information systems for unsatisfactory reductions in face-to-face communication. Some users complain that the EHR creates an "illusion of communication,"[16] where users believe that information entered into the system will be somehow communicated to the relevant personnel. This assumption can result in missed or delayed execution of orders or failure to appreciate the recommendations of a consultant. Users may erroneously assume that allergies entered into the system will adequately protect patients from receiving offending food or drugs.

No installed EHR can remain static for long. Maintenance, revisions, and upgrades of both software and hardware contribute to constant flux. Consequences should be expected with every change, and many changes require testing that can become onerous. Although minor changes can occur without supplemental training of personnel, failure to provide training for some changes can cause significant user frustration and errors. Some configuration changes requested by one group may also adversely affect other users in unexpected ways. Mechanisms must be developed to resolve conflicts of this nature. As clinicians become increasingly dependent on the system, pressure to keep the system operational mounts, requiring around-the-clock technical support.

Human Factors Engineering

Cognitive science, computer science, and human factors engineering are among many disciplines that can facilitate development of a successful EHR system. Human factors engineering investigates human capabilities and limitations and applies that

knowledge in the design of systems, software, environments, training, and personnel management. Application of human factors considerations in developing an EHR can maximize successful design and implementation of these systems. Some human factors principles may seem self-evident but can be overlooked when not approached systematically. Developers must understand the users, undertake detailed task analyses, and assess computer-supported cooperative work—the study of how people work within organizations and how technology affects them and their work. Three principles that may improve clinical information systems are accounting for incentive structures, understanding workflow, and promoting awareness of the activities of other group members. Institutional and personal incentives for using an EHR differ, but only the latter will effectively influence use. Awareness of the roles played by other team members enhances collaboration. Improving collaboration may decrease the incidence of medical errors.[19]

Another important area of human factors engineering relates to interface design. Interfaces should be simple and consistent, with important data highlighted, such as the patient name or weight. “Progressive disclosure” means that commonly used and important functions should be presented first and in a logical order, whereas infrequently used functions should be hidden but available. Minimizing the clinicians' cognitive load can be accomplished by displaying all relevant information together on one screen rather than relying on the user to remember critical bits of data from different parts of the chart. Potential user errors should be anticipated, and easy error recovery should be designed into the system. Error messages should be informative and could include advice about error recovery. Other feedback should be provided to acknowledge user actions, particularly when the system appears frozen. Given the chaotic health care environment, the interface should also be designed to forgive interruptions, allowing work to be saved and facilitating task resumption.

User satisfaction is an important predictor of system success. Satisfaction is enhanced when the systems are designed with the users' needs and preferences in mind. Peers who serve as advocates for their groups during development and subsequently teach other users generally increase acceptance of the systems. Ease of use, rapid response times, flexibility and customizability, mobile workstations, implementation of effective decision support tools, access to reference information, and adequate training and support are all important factors in enhancing both user satisfaction and system success.[20]

Implementation

Implementation of an EHR system requires an investment of additional staff, hardware, software, and an expanded communications infrastructure or network. For large hospital networks, the costs can be extremely high.

Developing an EHR requires careful planning and phased implementation. The specific needs of the institution must be examined, particularly with regard to the existing technology and practices. The process should be viewed as an opportunity to enhance care, rather than simply to replace the paper, and requires reassessment of existing practices and reengineering of health care delivery. As each incremental phase of implementation is approached, the focus should be on overcoming specific barriers to care rather than on the nebulous goal of “creating a paperless process.”[21]

Ensuring that the EHR satisfies every need involves considerable planning, designing, and testing. Even well-designed, off-the-shelf EHR systems can satisfy only 80% of the complex requirements of any multipractitioner organization. The remainder must be either adapted from other content or created from scratch. Substantial "expert" direction from teams of physicians, nurses, other allied health care providers, and medical records and financial staff is required to assist in developing the design and implementation of all EHRs.[22] If clinicians abdicate their responsibility in participating in this process, they are virtually ensuring that the resulting system will fail to satisfy their needs. Physician acceptance and participation can be enhanced by acknowledging the importance of physicians in the process, training them early and often, frequently and routinely eliciting their feedback, and demonstrating responsiveness to their needs and concerns.

Clinical Decision Support

According to the American Medical Informatics Association definition, "clinical decision support systems provide clinicians, staff, patients, or other individuals with knowledge and person-specific information, intelligently filtered or presented at appropriate times, to enhance health and health care." They further specify: "It encompasses a variety of tools and interventions such as computerized alerts and reminders, clinical guidelines, order sets, patient data reports and dashboards, documentation templates, diagnostic support, and clinical workflow tools."[23] These systems are not intended to make clinical decision but to provide context-specific knowledge and enable the ultimate decision makers, who are the clinicians, patients, and health care organizations, to make better decisions.[24]

As discussed earlier, there is currently a disconnect in the US health care system between the growth of medical knowledge and the increasing concerns about suboptimal care and rising costs.[23,24] The implementation of CDS systems has been proposed as the tool to close the gap between the generation of new knowledge and its application to practice in order to optimize care while reducing unnecessary costs.[25] However, most CDS systems currently in use are associated with vendor EHRs and have a limited scope. The greatest adoption has been in the form of simple alerts, order sets, prescription templates, drug-allergy, and drug dose checks. This type of basic CDS has had a modest impact on quality of care and reduction of errors,[15] highlighting the importance of investing in the development and adoption of advanced CDS systems. The Institute of Medicine recommends that health care providers and organizations invest in CDS systems and make them a routine feature of health care delivery.[3] It is indeed the responsibility of clinicians and the organizations in which they work to promote the optimal use of knowledge and best practices in the clinical decision-making process, and CDS systems hold the potential to make such practice a seamless part of patient care.

CDS systems can be generally categorized into three different types[24]:

- Alerts, reminders, and recommendations
- Medical knowledge databases and "infobuttons"
- Dashboards, data visualization, and templates

Alerts, Reminders, and Recommendations

Alerts, reminders, and recommendations are the most widely used type of CDS, most of them integrated in EHRs or computerized provider order entry (CPOE) systems. Drug-drug interaction, drug-allergy, and drug dose checks are some examples of these basic CDS, which are usually triggered by one or two pieces of patient-related information. Reminders such as immunizations due or age-based health screenings also fall into this category. Recommendations such as order sets and order sentences are also included in this category. Order sets have received much attention in the CDS literature, mainly because they provide straightforward CDS within CPOE systems, they are easy and faster to use than writing single orders, and they deliver just-in-time, evidence-based prompts.[26] A prospective study looking at the effect of CPOE with CDS implementation in a pediatric ICU found a 99.4% reduction in prescribing errors and a 40.9% reduction in potential adverse drug events.[27]

Another type of alerting system that is starting to make its way into clinical practice is the application of real-time algorithms on physiologic monitoring data to predict events and alert clinicians. In neonatal medicine, the most prominent of these is the analysis of heart rate variability and changes over time to predict sepsis, which has been subject to a large randomized control trial showing a significant reduction in mortality.[28] A study of this scope has not yet been performed in the pediatric critical care setting, but this type of physiologic waveform analysis and algorithm development is currently an active area of research with a lot of promise in the field of critical care.[11]

Medical Knowledge Databases

Medical knowledge databases have flourished with the advent of widespread Internet access in patient care. These databases might be connected to EHRs and have the capability of retrieving highly relevant online documents through the so-called “infobuttons.” An example of this is the Lexicomp Drug database that can be accessed from many EHRs to find information about a specific drug. Another example of this type of resource is UpToDate, an online database with almost 10,000 peer-reviewed medical articles with diagnostic and management recommendations, which can be used as a stand-alone resource or through an EHR interface. When these resources are accessed from an EHR, it is often through an infobutton, which, when clicked, performs a patient- or condition-specific query of the knowledge database. Health Level Seven International (HL7), the standard development organization, has created a standard for “context-aware knowledge retrieval,” which has been implemented in many commercial EHRs as an infobutton manager. Full-text electronic resources have seen increased use among trainees,[29] but their success at meeting knowledge needs and supporting clinical decisions has not been systematically studied. The reality is that clinicians continue to have many informational needs in everyday practice and those needs are frequently unmet.[30]

Dashboards, Data Visualization, and Templates

Dashboards, data visualization, and templates have not received much attention in the CDS literature until recently, but they represent an upcoming area of research.

The principle behind the use of these tools is that good decisions are not only based on having the right information but also in how the information is consumed. CDS systems that take into account the increasingly important aspect of human-computer interaction and make use of data visualization tools and information displays in an optimal way can make a significant impact in the clinical decision-making process.[24]

An interesting area of research that focuses on information consumption in the ICU is the redesign of electronic interfaces to support and improve clinical decision making. Researchers at Mayo Clinic have shown that in a simulated scenario of critically ill patients, the use of an interface containing only highly relevant information organized around organ systems was associated with reductions in task load, time to task completion, and errors of cognition when compared with a standard EHR interface (Fig. 12.3).[31]

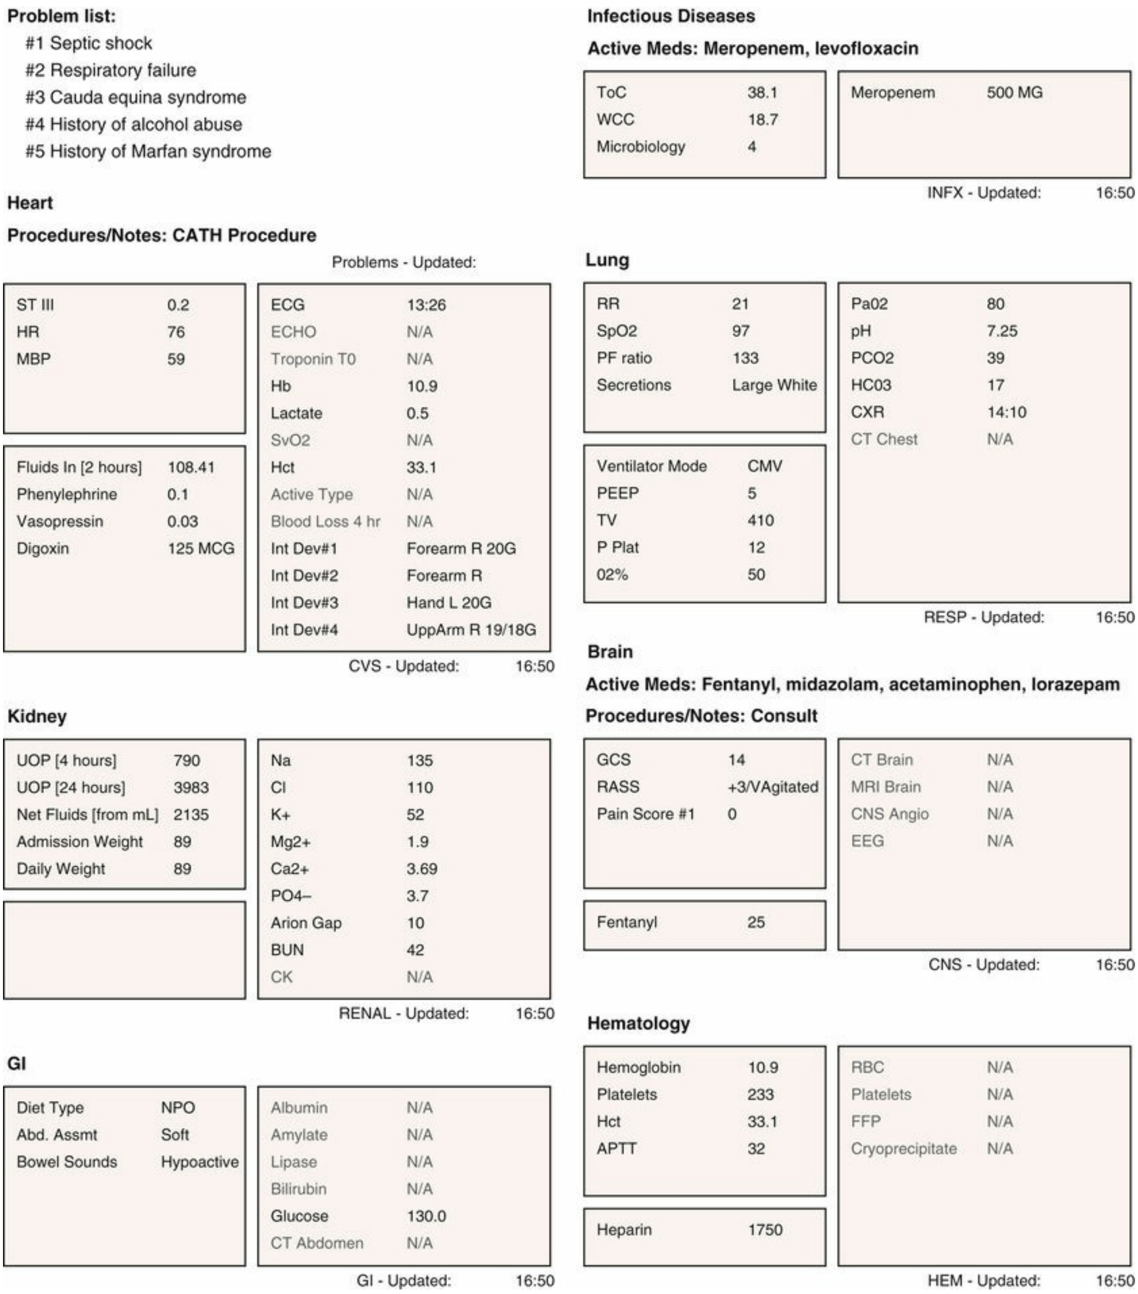

FIG. 12.3 Interface with highly relevant information organized around organ systems designed by the research team at Mayo Clinic. (From Ahmed A, Chandra S, Herasevich V, et al. The effect of two different electronic health record user interfaces on intensive care provider task load, errors of cognition, and performance. Crit Care Med. 2011;39:1626-1634.)

CDS Effectiveness

The study of CDS effectiveness, along with other health information systems and applications, such as CPOE, has always been limited by variability in the quality of the systems. Having said that, a large systematic review of 148 randomized controlled trials that evaluated the effectiveness of CDS systems of both locally developed and commercial systems showed moderate to strong evidence that CDS can reduce morbidity, reduce cost of care, increase the rate of ordering recommended treatments and other services, and increase health care provider satisfaction.[15] The review did not show an overall impact on length of stay, mortality, efficiency, or health care provider acceptance. Another review of CDS systems, this time in the pediatric ICU, also found some studies showing a positive impact of these systems in the process of care but noted the importance of human factors, implementation, and usability aspects of these systems as key factors in their success.[32]

Within the literature there are also many examples of CDS systems that have fallen short of the intended goals or have resulted in unintended consequences.[16] An example of this is a study that showed using a hard stop alert for changing prescribing behavior within a CPOE in which the order was blocked from further execution when the alert was triggered was effective at preventing the order from being placed, but it also delayed the treatment of patients who needed immediate drug therapy.[33]

It is clear that much more research and development needs to occur in order for CDS systems to fulfill their role in the transformation of our health care system, as has been proposed by the Institute of Medicine and other organizations. More rigorous research to support the content and deployment of these systems, more robust and controlled development and validation methodologies, and better dissemination and implementation practices are all necessary steps before CDS systems will achieve their full potential.

Patient Safety and Technology in the ICU

Patient safety concerns remain paramount in any hospital system, including clinical information systems.[34] To the extent possible, redundant systems should be in place to minimize the effect of the failure of a single component. Robust down-time contingency plans must be developed should the clinical information systems cease normal function in either planned or unplanned situations. These contingency plans must account for continued data acquisition and retrieval and provide for mechanisms for communication among health care providers and services. Users should be informed about recovery procedures and what they mean to the clinical database. Do backlogged data generated during the down time ever enter the system? How are they timed? Or is there a gap in the clinical information that the

clinicians must fill in for themselves if they want the whole picture?

Many anomalous circumstances related to the EHR can threaten patient safety. Data, such as a laboratory value or a physician order, can be entered into the wrong patient record and prompt the clinician to respond appropriately but on the wrong patient. Similarly, data can be displayed in ways that are so confusing that they are interpreted incorrectly.

Default behaviors of portions of the EHR should be designed carefully because busy or distracted clinicians may accept the default without understanding what they are accepting or without considering the consequences. For example, default drug dosing options for renally cleared medications, which might be appropriate for most patients, might not be safe for neonates and patients with renal dysfunction.

Automated Adverse Event Detection

Children are at significant risk for adverse events. By an estimate, every day a child spends in a pediatric ICU in the United States, his or her cumulative risk for an adverse event increases by almost 7%.[35] Traditional methods used to detect adverse events in children included manual chart review and voluntary incident reporting. These detection systems are inefficient and significantly underestimate the number and prevalence of adverse events.[36]

Another detection strategy relies on trigger methodology where an occurrence, found on manual chart review, triggers further investigation to determine the presence of an adverse event.[37] For example, the administration of flumazenil may trigger the detection of benzodiazepine-induced respiratory depression. Automated adverse event detection relies on the generation of a trigger report from the EHR, which indicates the possibility that an adverse event has occurred, requiring further investigation. This methodology has been proven an efficient and cost-effective way to detect adverse events. Other more advanced algorithms for detection of adverse events have been tested, and even though some have been successful, further research and development are necessary in this area.[38]

Smart Infusion Pumps

Errors related to intravenous infusions are often associated with significant harm in the pediatric ICU. A study involving pediatric inpatients noted that intravenous infusions were associated with 54% of potential adverse drug events.[39] Furthermore, adverse drug events associated with intravenous infusion devices generally result from incorrect programming. Smart infusion pumps represent an improved form of pumps, and a recent systematic review showed that they significantly reduced programming errors.[40]

Most intravenous infusion pumps in use today have the flexibility and capacity to deliver a wide range of infusion rates and volumes. In an effort to standardize pump systems throughout an organization, the same device may be used to deliver medications to an infant or adolescent. Therefore significant dosing errors can be easily programmed by a bedside provider if there are no double checks or electronic decision-support systems in place. Smart infusion pumps contain sophisticated software that allows for programming medication safety libraries within each pump. In addition, these devices may be queried to allow aggregation and analysis of data

regarding infusion practices for quality improvement purposes. Furthermore, some pump vendors offer the ability to connect the device via a wireless network to allow bidirectional flow of information to and from the pumps.

Smart infusion pump medication libraries include drug name, usual concentrations, and dose range checking to avoid high or low dosing for both infusion and bolus dosing. Generally these libraries are created for a given patient care unit, patient population, or provider group. Providers who attempt to program the pump beyond the limits set in the library will encounter an alert that may either be overridden (soft alert) or not overridden (hard alert). The impact of smart infusion pump technology on patient safety is not completely clear at this time. These devices must be paired with optimal design and process change in order to achieve meaningful outcomes.[40]

Medication Bar Coding

In 2004, the FDA published a "Bar Code Rule" mandating manufacturers and repackagers to have a bar code of the National Drug Code on the immediate drug containers label.[41] An integrated system that includes bar coding of medications focuses on preventing errors in drug administration, which may represent up to 38% of medication errors.[42] The essential components for safe medication administration using bar code technology revolve around the "five rights": the right patient, right drug, right dose, right route, and right time. In bar code medication administration, the nurse uses a bedside scanning device to scan the medication, patient's wristband, and nurse's identification. A query is then sent to the EHR to the patient's medication orders. A match on the five rights then signals the nurse that the medication may be administered. Though bar code medication administration systems have been associated with error prevention, they have also been associated with new types of errors, such as those introduced when a busy nurse has to select a medication from a list and document the administration time using a keyboard and mouse.[43] Proper implementation is key to achieving value with these systems.

Privacy and Security of Health Information

Privacy of Health Information

Ensuring the privacy of personal health information has always been a concern, but the availability of this information in electronic form raises new concerns because securing it is not a simple matter of putting it under lock and key. In legislating the Health Insurance Portability and Accountability Act (HIPAA) to protect health insurance coverage for workers and their families when they change or lose their jobs, Congress also sought to alleviate some of the administrative burdens on health care providers by mandating standards for electronic data interchange. Because electronic transactions between providers and insurers would become easier, and more personal health information would become available in electronic form, privacy and security rules were incorporated into the legislation. These rules apply specifically to protected health information (PHI), which is any health information that can be linked to an individual (Box 12.1).

Box 12.1

Elements Considered Protected Health Information

Names

All elements of dates (except year) for dates directly related to an individual, including:

Birth date
Admission date
Date of procedure
Discharge date
Date of death
Telephone numbers, fax numbers
Electronic mail addresses
Social Security numbers
Medical record numbers
Health plan beneficiary numbers
Account numbers
Certificate/license numbers
Vehicle identifiers and serial numbers
Device identifiers and serial numbers
Web URLs
IP address numbers
Biometric identifiers, including fingerprints and voiceprints
Full-face photographic images and any comparable images
All geographic subdivisions smaller than a state, including:
Street address
City
County
Zip code, and their equivalent geocodes
Any other unique identifying number, characteristic, or code

The privacy rule applies to protected health information whether it is stored in electronic form or not. The rule limits the nonconsensual use or release of protected health information, gives patients new rights to access their medical records and to know who accessed them, restricts most disclosures of health information to the minimum needed for the intended purpose, establishes penalties for improper use or disclosure, and establishes new requirements for access to records by researchers and others. The impact of HIPAA on research relates to consent paperwork that safeguards the privacy of patients participating in research, simplified guidelines regarding the limited circumstances where patient health information can be used for research purposes without authorization by the research subject, and clarifying methods by which protected patient health information can be de-identified so that such information can be disclosed freely.[44]

With regard to health data integration and sharing, the concept of privacy can be considered a double-edged sword: too much risks blocking progress and limiting research; too little risks loss of public trust and confidence and potentially undermines a well-intended effort.[45] Both overregulation and underregulation have their problems, and striking a balance is essential. In a survey for clinical scientists

on patient privacy and its effects on research, most of the respondents felt that the HIPAA Privacy Rule did not enhance privacy for patients and resulted in increased difficulty to complete research studies.[46] For these and other reasons, the Institute of Medicine recommended in their *Best Care at Lower Cost* report to "streamline and revise research regulations to improve care, promote the capture of clinical data, and generate knowledge."[3] The Institute proposed two strategies to achieve this goal: 1) to expand and accelerate the review of HIPAA and institutional review board policies and address the potential impediments they might be causing to research and 2) to engage patients, clinicians, health care organizations and other stakeholders to develop strategies that improve the understanding of the benefits of using clinical data in meaningful ways.

Security of Health Information

The security of a networked system involves at least three components: physical security, prevention of unauthorized access, and protection from malicious software.

Physical access to sensitive portions of the system must be secure. Servers should be in locked rooms with controlled access. Networking closets with wiring and hubs should be locked. Sensitive equipment must be protected from extreme temperatures, fire, and water damage. Backup power sources are required. Workstations, wherever possible, should be in open areas where their use can be monitored but not so open that unauthorized persons can peer over a user's shoulder to steal a user name and password or see sensitive information. Physical security also involves ensuring that the data are backed up and readily accessible whenever they are needed.

Preventing unauthorized electronic access involves blocking attacks from the outside and authenticating legitimate users before allowing them access. Wireless networks must be configured to minimize the risk of intruders tapping into the system. Systems can be attacked by malicious software, loosely labeled as viruses. Securing systems from these threats is becoming increasingly challenging.

The HIPPA Security Rule attempts to provide a uniform level of protection of all protected health information that is housed or transmitted electronically. These standards mandate safeguards for physical storage and maintenance of equipment that contains patient data. Network closets and servers should be locked up, and data must be backed up. The displays of computers in public areas should be turned away from open view, and screens should be installed to limit the viewing angle. Storing protected health information on computers in unlocked offices, on laptops, or on removable media such as flash drives is prohibited unless the data are encrypted. Users should log out of applications that access PHI when those applications are no longer needed. Access to data must be limited to authorized personnel on an as-needed basis with clear administrative policies for granting and revoking those privileges. There must also be technical safeguards to prevent unauthorized intrusion into networks or interception of transmissions over open networks. Firewalls should protect hospital networks, particularly if there are wireless access points. PHI should never be sent by email without encryption because standard email is inherently insecure.

Telemedicine

Telemedicine in pediatrics refers to use of electronic communications technology to provide health care for infants, children, adolescents, and young adults when geographic distance separates the clinician from the patient, caretaker, or referring practitioner.[47] Pediatric subspecialties, including critical care, have experimented in telemedicine for decades, and evidence suggests that such care is both clinically and cost-effective. Although many technical, legal, and financial hurdles remain, telemedicine remains a viable and valuable care delivery model for critical care.[48]

Even though intensivist coverage in ICUs is associated with a reduction in mortality and resource utilization,[49] the cost and shortage of intensivists can preclude hospitals in areas of need from providing these services. Despite the fact that "tele-ICU" care cannot replace on-site expert care, studies have shown that the use of telemedicine can result in higher quality of care, more efficient resource utilization, and higher satisfaction by patients and providers.[48,50]

The cost of implementation of a telemedicine program in an ICU can be substantial—in the order of tens of thousands of dollars per monitored bed—which can play a significant role in its cost-effectiveness.[51] Many programs use fixed cameras and microphones in patient rooms and remote connections to physiologic monitors and EHRs.[50] Robots can even roam between patient's rooms.[52] Using today's advances in technology, it is also possible to implement it inexpensively with a mobile computer configured with a web cam and wireless connection[53] or even by staff members armed with a smartphone.

"Big Data" in Critical Care

The digitalization of health care is opening the door to an era of big data in medicine. Larger and larger datasets of biomedical information will become available to researchers in every field of health care, providing an opportunity to gain tremendous insight from them. Data from genomic, proteomic, physiologic monitoring, imaging, operational, and financial datasets are starting to enrich clinical data warehouses everywhere, but much of that data still remains underanalyzed.[54] If we develop the appropriate infrastructure to learn from these data and use it to improve care, we could benefit from the disruptive phenomenon of big data, much like the retail, manufacturing, and financial industries have done.[4]

Biomedical advances and the availability of massive amounts of patient-related data also come with an inevitable consequence: a growing knowledge gap. While medical knowledge continues to grow exponentially, the cognitive capacity of a human brain remains fixed. David Eddy, one of the fathers of evidenced-based medicine, eloquently said that "the complexity of modern medicine exceeds the inherent limitations of the unaided human mind,"[55] and that was more than a quarter of a century ago. The reality is that clinicians, like other human beings, are excellent at pattern recognition but significantly underperform with complex information processing tasks.[54] Evidence shows that the human brain cannot simultaneously consider more than about four pieces of information at one time in order to make a decision, something that is increasingly misaligned with today's health care environment. Advanced analytic algorithms and decision support systems could bridge this knowledge gap by sifting through the deluge of data,

performing complex processing tasks, and presenting the bedside clinician with the most relevant pieces of information about the patient in order to enhance the decision-making process. Whether this will become a reality of everyday medicine remains to be seen.

Critical care medicine could especially benefit from big data–driven research. On the one hand, we routinely use many interventions and practices in the ICU that lack evidence to support them in an evermore complex clinical environment and on the other hand, we have a tremendous amount of structured data being generated by a myriad of monitoring devices, laboratory tests, and clinician charting that could be analyzed to improve our understanding of critical illness and the therapies we use. Some experts advocate the development of highly detailed critical care databases in order to inform the design of clinical investigations, develop decision support systems, and test clinical algorithms using real-world data.[11]

Health Analytics

A health analytics program, also known as health data mining or data science program, is a data-driven research and development program within a health care organization. While the emphasis of such a program might range from the purely clinical to a more business/financial focus, the common goal of health analytics programs is to exploit the data resources in an organization to improve processes, reduce costs, and provide better care.[54] A health analytics program requires competencies in several areas of the data life cycle, and a multidisciplinary team composed of clinicians, engineers, statisticians, and other stakeholders is most likely to produce the most beneficial program. Three key areas of a health analytics program are:

1. *Data management*. This includes data capturing, aggregation, and structuring for analysis, as well as the overarching competencies of data governance and quality assurance. Data management is probably the most resource intensive of the components of a health analytics program and requires a significant institutional commitment.

2. *Statistical learning.* The analysis of large biomedical data can be performed using traditional biostatistical analyses, as well as machine learning algorithms, which become necessary with more complex, multidimensional datasets. The goal of the statistical learning is to apply mathematical principles to the data in order to describe past events, understand current trends, and build prediction models.

3. *Information and knowledge delivery.* The final step in a health analytics program is possibly the most critical step. How effectively the insight gained from the data is delivered to the decision makers can determine the success of a program. Less sophisticated modes of information delivery such as reports or alerts will likely have a lower impact than more advanced forms of clinical decision support, predicative modeling, or systems optimization.

Clinical Data Research Networks

As the advanced analytic capabilities of individual health care organizations are

developing, there is another important trend in health care: the aggregation of clinical data across institutions. Integrating data from multiple databases to form repositories for new discovery is not an easy task. Several barriers, both technical and nontechnical, such as security, interoperability, privacy, and data ownership, can limit the scope of these projects, but there are promising new initiatives taking place.

One of the most notable initiatives is the clinical research network proposed by the Patient-Centered Outcomes Research Institute (PCORI).[56] PCORI was created under the Affordable Care Act of 2010 to promote comparative effectiveness research across the United States. PCORnet, the National Patient-Centered Clinical Research Network, is a PCORI-based initiative to create a large, highly representative network for conducting clinical outcomes research. PCORnet's proposed infrastructure is composed of 11 health system–based networks and 18 patient group–based networks, and its goal is to generate interoperable datasets to support multinetwork observational and randomized clinical studies.[57]

The pediatric community has long made use of the Pediatric Health Information System (PHIS), a clinical-financial claims database with more than 6 million cases. PHIS is currently embarking on a proof-of-concept project called PHIS+ with the specific aim of developing the infrastructure to link laboratory results and radiologic reports from six large children's hospitals in the United States to the administrative data from PHIS in order to enhance its granularity and facilitate research.[58]

The true value of these clinical data research networks cannot yet be predicted, but there can be no argument that the limitation of most studies in pediatrics and critical care is currently the paucity of data available from single institutions. In aggregate, who knows what we may learn?

MIMIC Database

The Multi-parameter Intelligent Monitoring in Intensive Care (MIMIC) database is a public-access database containing clinical data for more than 40,000 adult and neonatal ICU patients from Beth Israel Deaconess Medical Center in Boston, Massachusetts, and is hosted by the Laboratory of Computational Physiology at the Massachusetts Institute of Technology.[11] MIMIC, which is now on its second version, also contains physiologic waveform data from monitoring devices for about a fourth of its patients. In addition, researchers from around the world routinely contribute series of patients to the database with physiologic waveform data from devices such as electroencephalograms, near-infrared spectroscopy monitors, and fetal electrocardiograms. The clinical data in MIMIC is de-identified and has been shared with more than 600 researchers from more than 32 countries, and it has been used to produce hundreds of peer-reviewed papers. MIMIC is offered along with numerous open-access toolkits to facilitate tasks such as query building, data visualization, and time-series analysis. It is an excellent research resource for the critical care community, and even though it does not contain any pediatric ICU patients at this point, there are plans on making that addition in future versions of the database.[59]

Virtual Pediatric ICU Systems

In collaboration with the National Association of Children's Hospitals and Related

Institutions, Child Health Corporation of America (now the Children's Hospital Association), and the National Outcomes Center located at Milwaukee Children's Hospital and Medical System, the Virtual PICU, funded by the Children's Hospital Los Angeles and the L.K. Whittier Foundation, developed a data collection tool specifically designed to understand pediatric critical care, the distribution of demographics, diagnoses, and outcomes and to form a basis for clinical research, quality improvement, and, ultimately, comparative data analysis. Over the years, there has been a significant expansion of the database, and it has evolved into a comprehensive tool for quality improvement and benchmarking.[60]

As of 2014, there are 119 PICUs participating in the web-based application of Virtual PICU Systems (VPSs) that now includes more than 1 million patient admissions. Affiliated institutions participate in an advisory committee, a users' group organization with annual meetings, and a research committee. They also receive periodic comparative quality reports detailing the performance of their ICUs along multiple axes, modeled on the Institute of Medicine's “Six Dimensions of Quality.”

The VPS database has been used extensively to inform pediatric critical care research. Merely providing demographics and descriptions and diagnostic patterns in critical care has aided the design of multiple national research projects and National Institutes of Health–funded projects. However, the core purpose of the prospective data collection is quality improvement, allowing comparative data reporting against comparable but unidentified institutions. These reports enable intensivists to objectively demonstrate the quality of the care they provide.

Conclusion and Future Directions

Medicine is an information service, and critical care is perhaps the most information-intensive medical subspecialty. It is no accident that many intensivists have a particular interest in health IT, but every practitioner will be more effective if he or she obtains the skills to better manage the flow of information. Furthermore, as physician leaders focusing on health IT, intensivists can lead the way in creating a safer environment for all patients. Understanding the limitations and pitfalls of the technology and exercising caution as it is implemented is of paramount importance for success.

As everyday users of health IT, intensivists should understand the threats to privacy and security, not only for our patients but also for ourselves. Systems are as vulnerable as their weakest link. Sustained vigilance and safe computing practices are essential to avoid calamitous data loss or exposure to exploitation.

The wider adoption of health IT is also fueling new trends in data sharing, analytics, and collaborative research, at a scale never before seen in health care. The impact that this can have in the practice of medicine has yet to be determined, but as frontline care providers of the most vulnerable and information-intensive patients, intensivists must continue to play a central role in the development and use of information technologies in our field.

CHAPTER 13

Building Partnerships

Patient- and Family-Centered Care in the Pediatric Intensive Care Unit

Jonna Derbenwick Clark

" 'Intensive care unit.' Wow, those are scary words for parents to hear! … We viewed the intensive care unit as a place people went when their medical situation was desperate or where they were likely to die."[2]

PEARLS

- Patient- and family-centered care (PFCC) uses an "innovative approach to the planning, delivery, and evaluation of health care that is grounded in a mutually beneficial partnership among patients, families, and providers."[1]
- Fundamental principles of PFCC include:
- Honoring differences and respecting each individual patient and family
- Maintaining flexibility in practice, policies, and procedures to fully accommodate the needs of patients and families
- Sharing honest and consistent information using collaborative communication
- Using a transdisciplinary approach to provide optimal support for the family unit
- Developing a partnership built on mutual respect among health care providers, patients, and families
- Empowering patients and families to participate in shared medical decision making
- Incorporating PFCC into practice improves patient and family satisfaction, reduces stress and anxiety, fosters the parent-child relationship, and ultimately

increases the quality, efficacy, efficiency, and safety of health care delivered.
- Overcoming real and perceived barriers to incorporating PFCC into practice requires an explicit, collaborative, and transparent approach involving all stakeholders to identify creative solutions.

Many parents share this perspective when faced with the hospitalization of a critically ill child.[2] These families not only face the extreme crisis of having a sick child whose life may be threatened; they are forced into a foreign environment and culture that can be intimidating, overwhelming, and perceived as unwelcoming. Families in the ICU are at one of the worst moments in their lives and suffer from an extreme level of stress, where they may feel powerless and out of control. This level of stress creates short- and long-term consequences, as many parents and children face severe emotional distress, which may result in posttraumatic stress disorder (see also Chapter 10).[3-7]

In order to mitigate the severity of this stress response and optimize the quality of medical care provided, patient- and family-centered care (PFCC) is a philosophy that highlights the importance of including the patient, when possible, and family in the provision of health care. The American Academy of Pediatrics (AAP) acknowledges that the "family is the primary source of a child's strength and support" and defines PFCC as "an innovative approach to the planning, delivery, and evaluation of health care that is grounded in a mutually beneficial partnership among patients, families, and providers."[1] PFCC can be incorporated across the spectrum of health care, from home to outpatient to inpatient, and is essential for the provision of high-quality care in the intensive care unit. Ongoing research in this area demonstrates that parent participation in the care of a hospitalized child directly benefits the child by reducing anxiety, improving cooperation, improving activity level, and reducing the length of stay.[8] Additional data reveal more effective utilization of health care resources, reduced health care costs, and improved provider satisfaction.[1]

Definition of "Family"

In the delivery of PFCC, patients and families, rather than health care providers or the legal system, define their families.[9,10] Because family structures are heterogeneous and evolve over time within a variety of cultural contexts, the term *family* requires a broad definition, referring to "two or more persons who are related in any way—biologically, legally, or emotionally."[9,10] A wide variety of family structures exist, including blended families, single-parent households, adoptive homes, same-sex couples, and transgenerational models where extended family members, such as grandparents, aunts, uncles, or siblings, serve as the primary caretakers.[7,9,10] Although health care providers and institutions have a legal obligation to respect the law regarding surrogate decision making for minors, they also have an ethical and professional obligation to respect the broader definition of family in practice, acknowledging that the family is the primary source of strength and support for the child.[1,8]

Historical Evolution of Patient- and Family-Centered Care

The conceptual aspects of PFCC date back to the 1950s, when studies demonstrated a negative impact of maternal-child separation, leading to a shift toward encouraging parent participation in the care of the hospitalized child.[1,8,10,11] In 1983, the Committee on Hospital Care and Pediatric Section of the Society of Critical Care Medicine published *Guidelines for Pediatric Intensive Care Units*, highlighting that, "Parents should be allowed to stay with the critically ill child as much as possible."[12] These guidelines explained that the presence of parents may lead to faster recovery, stating, "The familiar face and voice of a parent may reach a child who appears comatose but is beginning to respond to stimuli."[12] In the following 2 decades, there was extensive research in the value and benefit of PFCC in health care communities. Several national organizations were founded, including Family Voices, an organization that advocates for family-centered, community-based services for children with special needs, in addition to the Institute for Patient- and Family-Centered Care, an organization that helps foster partnerships among health care professionals, patients, and families to advance family-centered care in health care settings.[1] More recently, several national organizations including the Institute of Medicine (2001), Maternal and Child Health Bureau (2005), American College of Critical Care Medicine (ACCCM) Task Force (2007), and American Academy of Pediatrics (2012) have furthered this approach by developing guidelines and endorsing that PFCC is essential to the provision of high-quality care.[1,13]

Fundamental Needs of Patients and Families in the ICU

Because of the complexity and intensity of the pediatric intensive care unit (PICU), families' needs are high. Although specific needs of the individual patient and family are important to consider, there is consensus that most families share similar needs including: 1) honest, accurate, and up-to-date information; 2) close proximity to the patient; 3) timely notification of any changes in the patient's condition; 4) assurance that the health care team cares about the child and that the patient is receiving excellent care; 5) access to resources to meet basic physiologic needs; and 6) feeling that there is hope.[7,14-17] Research demonstrates that provider perceptions often underestimate the needs of families. Furthermore, when families' needs *are* known, they are not adequately addressed in practice. Unfortunately, when families' needs are not met, there is a negative impact on satisfaction with care, in addition to a greater amount of stress and anxiety.[6,7,17]

Core Principles of Patient- and Family-Centered Care[1,11]

The practice of PFCC, in which patients and families are treated as integral partners with the health care team, is now recognized as the standard of care in pediatric critical care medicine.[1,11] Borrowing from the framework established by the AAP, the

following discussion highlights each of the fundamental principles of PFCC within the context of the pediatric intensive care unit[1] (Box 13.1).

Box 13.1

Core Principles of Patient- and Family-Centered Care

- Honor differences and demonstrate respect for each individual child and her family
- Maintain flexibility in procedures, policies, planning, and delivery of health care
- Share information using collaborative communication through a variety of approaches, including written information, bedside updates, family-centered rounds, and transdisciplinary care conferences
- Provide informal and formal support for the child and family using a transdisciplinary model of practice
- Collaborate with patients and families through the development of a partnership at all levels of health care
- Empower patients and families to participate in shared medical decision making

Adapted from American Academy of Pediatrics. Patient- and family-centered care and the pediatrician's role. Pediatrics. 2012;129:394-404.

1. Honoring Differences and Respecting Each Child and Family

One of the most fundamental aspects of developing a "mutually beneficial partnership" with patients and their families requires a relationship of mutual respect, in which differences among the stakeholders are honored.[1] The AAP states, "Listen to and respect … each child and family's innate strengths and cultural values. Honor racial, ethnic, cultural, and socioeconomic background and patient and family experiences."[1] Recognizing that one individual cannot be an expert on all cultures, faiths, ethnicities, spirituality, or religious practices, practicing cultural humility is crucial, acknowledging biases and assumptions.[18] All admissions to the ICU are extremely distressing, whether a child suffers from acute respiratory failure due to respiratory syncytial virus or has multiple organ dysfunction syndrome following a bone marrow transplant. Patients and families demonstrate a wide range of responses within their own social construct, using a variety of coping mechanisms to overcome the distressing state.

In the ICU, where major medical decisions regarding life, death, and quality of life are often made in a short time frame, differences in beliefs and value systems may be accentuated among health care providers and families. Furthermore, in an environment of extreme stress, where patients and families are in state of crisis, tensions between the stakeholders may be exacerbated. Taking the time to listen to different perspectives and understand how knowledge, past experiences, and value

systems impact decisions is essential. In the majority of situations, families and health care providers desire what is in the best interest for the child. Acknowledging that values and belief systems affect perceptions of what actions are in the best interest for the child can be helpful when navigating challenging circumstances. For example, parents of a beloved child who suffers from a life-threatening illness with a poor prognosis may choose to prolong life as long as possible, treasuring and valuing each day they have with their child alive, while health care providers may view prolonging life as merely prolonging suffering. Developing a collaborative relationship ensures that differences in opinion are respected.

For non–English-speaking patients and families, where fundamental communication and language barriers exist, developing a partnership built on trust and understanding may be especially difficult. The use of in-person language interpreters and cultural navigators who serve as health care guides for the family and cultural guides for the health care providers is essential to building this relationship. Optimizing additional means for communication with non–English-speaking families, such as a video interpreter service, can also be beneficial.

2. Maintaining Flexibility in Practice and Procedures to Deliver Health Care Within the Context of the Family

The PICU is a highly complex environment that requires a systematic approach to policies and protocols to ensure the delivery of efficient, effective, and safe health care. When developing these policies and protocols, it is essential to recognize how these systems and processes impact patients and families. Hospital systems and organizations need to "ensure flexibility in organizational policies, procedures, and provider practices so services can be tailored to the needs, beliefs, and cultural values of each child and family."[1] Practices and procedures should "facilitate choice … about approaches to care."[1]

Historically, hospitals were designed as sterile environments that restricted visitation, with fear of spread of infection and the breach of confidentiality.[10] However, with the evolution of PFCC, many health care organizations and institutions are making the effort to better accommodate patients' and families' needs by including them in the planning and delivery of care. When a child is hospitalized in the ICU, the needs of the family are extremely high.[7,16,17] Addressing many of these needs can be approached considering the following categories: 1) visitation policies and physical accommodations for families, 2) family-centered rounds, 3) family presence during cardiopulmonary resuscitation and other invasive procedures, and 4) collaborative communication.[13,19] When assessing the potential benefits and harms of policies, procedures, and delivery of health care in these areas, open dialogue and transparency regarding the needs of all the stakeholders are essential, allowing for creative solutions when conflicts arise.

Geography of ICU

In planning and designing an ICU, the geography of the unit needs to accommodate both health care providers and patients and families. For example, a unit that allows for effective and efficient management of multiple critically ill patients is essential for health care providers, while patients and families need privacy, space in close

proximity to their child, and access to an area where they may find respite from the intensive environment to build strength and repose.[12,20]

Admission Process and Visiting Hours

Parents and family members should be treated as partners, rather than visitors, within the ICU. They should feel welcomed into the foreign environment through the use of a variety of communication styles, both spoken and written, and remain well informed of processes and procedures. In general, visiting hours for parents and primary caretakers should be nonrestrictive in order to optimize parent and child bonding.[13] However, maintaining flexibility in these visiting policies is important as there may be unique circumstances when limiting visitation by family members is necessary to create a calm and healing environment for the child.

Creating a "Personalized" Room

Patients and families should have the liberty to create an environment that mimics home, with decorations, photographs, favorite toys, and blankets as long as the modifications do not place the child at risk and do not interfere with the provision of medical care.[12,13] Although the ICU is a place of work for the health care providers, it is the bedroom for a critically ill child and potentially may be the last place a dying child spends time.[21] Creating a home environment is beneficial to not only the child but also the health care team in that it helps providers gain insight into who the child is as a person, enabling them to address the needs of the child more appropriately.

Sibling Participation

Siblings of critically ill children are severely affected and need to be supported according to the values of the family.[7,22] Siblings need maintenance of a familiar lifestyle, including family cohesion, distraction from the immediate crisis, hospital visitation, and developmentally appropriate information.[7] The transdisciplinary team, including child life specialists and social workers, can help educate parents and caregivers about anticipated questions and emotional responses that may occur and provide appropriate referral services and support systems.[22]

Parental Presence During Cardiopulmonary Resuscitation and Invasive Procedures

Numerous professional organizations, including the American Heart Association and ACCCM, endorse offering families the option to remain in close proximity to their loved ones during cardiopulmonary resuscitation and invasive procedures.[23,24] Allowing family presence has direct benefits for parents and caregivers, including improved satisfaction, better understanding, reduced anxiety, better coping, more emotional stability, and improved adjustment to a child's death.[24-26] Despite these potential benefits, the practice remains controversial. Clinicians raise concerns that parental presence may increase the risk for litigation and may impact technical performance, clinical decision making, and the ability to teach.[24,25] In a large single-center study, using formal practice guidelines and interprofessional education to prepare clinicians for parental presence, "few clinicians reported that parent presence affected their technical performance (4%), therapeutic decision making (5%), or ability to teach (9%)."[25] By developing protocols, institutional policies,

education, and dedicated staff resources to allow parental choice and provide support for parental presence during invasive procedures and cardiopulmonary resuscitation, these concerns can be minimized.[24]

Transition Points and Follow-Up Care, Including Bereavement

Once adjusted to the ICU, many families ultimately appreciate the high level of physician supervision and nursing presence, making transitions to the acute care floor potentially difficult. Supporting families through these transitions during the course of an illness is necessary.[27] For families who spend an especially long period of time in the ICU, providing families with realistic expectations and allowing the family to visit the acute care floor before transfer can be beneficial. In addition to providing additional support for transitions between different geographic locations in the hospital, developing a framework to help families transition through different approaches to care, from curative to life prolonging to comfort care, is important.[19] Furthermore, using a systematic approach to follow up with families following the death of child, with condolence letters and formal follow-up meetings, is also necessary to reduce the perception of abandonment and improve the bereavement process. (See also Chapters 15 to 16.)[16,28,29,30]

Sharing Information Using Collaborative Communication

High-quality communication with families is essential in the ICU where medical information is complex and detailed, high stakes decisions are required, and multiple teams of health care providers are involved.[31] While there is a spectrum of preferred decision-making roles of families, ranging from an independent and autonomous approach to delegating decisions to clinicians, most families need to be well informed.[5] Optimizing communication with families reinforces the development of a partnership with families, acknowledging the important role of parents and caregivers and their unique knowledge of their child. The AAP recommends, "sharing complete, honest, and unbiased information with patients and their families on an ongoing basis so that they may effectively participate in care and decision making."[1]

Over the past 2 decades, there has been extensive research in optimizing communication among health care providers, particularly in the ICU and surrounding end-of-life care decision making. (See also Chapter 16.)[30,32,33] In the ICU, information is shared using three different verbal models, including individual updates at the bedside, family-centered rounds, and formal care conferences. Written information may also be provided. Often a combination of all these approaches is necessary to optimize communication with patients and families. Depending on the educational, social, and cultural backgrounds of patients and families, in addition to different provider styles, a variety of approaches to communication may be used.

Elements of High-Quality Communication

Sharing medical information is complex and requires a high level of skill among health care providers (see also Chapter 4). Although using a variety of means to

communicate with patients and families is necessary, the language used and other specific elements are also important. According to parents, high-quality elements of communication include: "comprehensive and complete information; clarity of information with the use of clear language; ease of access to caregivers and their explanations through the course of care; pacing of information, soliciting of parents' emotional responses, and addressing their questions; consistency of information; honesty; lack of false hope; empathy as demonstrated verbally and nonverbally; effective communication; summary statements; and next steps."[22,33,34] A useful tool is the VALUE mnemonic, where family statements are *Valued,* family emotions are *Acknowledged,* the family is *Listened* to, the patient is *Understood* as a person, and family questions are *Elicited*.[35] This mnemonic emphasizes the importance of using collaborative communication, or a form of communication in which interpersonal communication and the relationship between the parties are "inexorably entwined."[19] Collaborative communication can accomplish at least five important tasks in PFCC including: 1) establishing a set of goals that guides collaborative efforts; 2) exhibiting mutual respect and compassion for each other; 3) developing sufficiently complete understanding of differing perspectives; 4) ensuring maximum clarity and correctness of what is communicated; and 5) managing intrapersonal and interpersonal processes that affect how information is sent, received, and processed.[19]

Particularly in the setting of the ICU, optimizing these elements of high-quality communication may be difficult due to the number of health care team providers involved and the short time frame in which news must be delivered. Therefore adequate training for all health care providers who interact with families is essential. In addition, when patients spend prolonged periods of time within the ICU, or have multiple subspecialty services involved, the identification of a continuity provider whose role is to maintain consistency in the health care plan while ensuring adequate communication with the family can be beneficial. Furthermore, using a team approach with respectful and excellent communication among team members, including physicians and nurses, ensures that clear, consistent, and comprehensive information is shared in an empathetic manner. Collaboration within the health care team results in improved overall outcomes in critical care including increased patient survival, decreased length of stay, and decreased readmission rates, in addition to improved patient and family satisfaction, decreased symptoms of anxiety and depression among family members, and reduced ICU nurse and physician burnout.[35]

Family-Centered Rounds

Rounds in the ICU serve several purposes including: 1) providing a setting for decision making related to the management of the child's care, 2) ensuring adequate communication among health care team members, and 3) allowing for teaching of medical students, residents, and other trainees.[36] Aligning with a patient- and family-centered approach, incorporating the patient, when possible, and family into these rounds fosters a partnership with the family. Although larger and more extensive studies are necessary to fully determine the benefits and potential barriers to this approach, many professional organizations endorse it. According to several pediatric studies, this approach improves family satisfaction, improves communication between all stakeholders, increases family trust in the medical team,

and potentially improves the quality of medical care provided, leading to shorter lengths of stay.[37-39] Several potential barriers and health care provider concerns regarding this approach include: 1) prolongation of rounds, 2) breach of confidentiality of protected health information, 3) reduced opportunities for teaching, and 4) concern for undermining trust of the health care team when different opinions are shared or teaching is done.[36,38,40] Although all of these concerns are valid, current evidence does not support them. On the contrary, family-centered rounds have demonstrated improved efficiency and communication because family concerns are addressed with clarity, preventing communication gaps and confusion. In addition, family presence usually lends itself to additional teaching opportunities.[38,40] Finally, when surveyed, the majority of parents are not concerned about privacy issues and therefore this concern can easily be discussed with parents on an individual basis.[36,38,40] To remain effective and efficient, using a family-centered approach to rounding requires thoughtful planning and following specific guidelines to streamline the process. Highlighting the purpose of rounds to all stakeholders and identifying explicit roles before rounds can help prevent misunderstandings.[36]

Structured Transdisciplinary Care Conferences

In critical care, where illnesses are life threatening and changes occur rapidly, sharing information with frequent updates at the bedside is crucial. Furthermore, in circumstances where medical decision making is highly complex, multiple subspecialties and disciplines are involved, or the severity of illness may lead to the demise of the patient, proactive and timely structured transdisciplinary care conferences may also be beneficial.[35] Although there is variability in the approach and style of these conferences, the palliative care and adult critical care literature provide a general framework for the facilitation of these conferences and highlight several tools.[19,35,41-43] In adult critical care, specific aspects of these conferences are associated with increased quality of care, decreased family psychologic symptoms, improved family ratings of communication, and improved outcomes. These aspects include timeliness (occur within 72 hours of ICU admission), private location for the conference, consistent communication by all members of the health care team, increased proportion of time spent listening to families speak, the use of empathetic statements, assurance that the loved one will not suffer, and providing explicit support for decisions made by the family.[35,41] Although additional research is needed to detail the benefits and potential negative aspects of this format for communication in the pediatric patient population, this approach should be considered as a potentially useful approach to optimize communication with families.

Providing Transdisciplinary Support for the Family Unit

Fundamental to PFCC is this mantra: “providing and ensuring formal and informal support for the child and family for each phase of the child's life.”[1] Due to the complex nature of pediatric critical illness and the high level of emotional distress triggered by hospitalization, a transdisciplinary team approach is necessary to provide full support for the patient and family, including siblings, who are at high risk for feeling abandoned and neglected. Acknowledging that patients and families enter the ICU with varying degrees of internal coping mechanisms in addition to

external support systems is critical to optimizing support.

Recognizing that all members of the health care team have different expertise, teams from a multitude of disciplines should be incorporated, when appropriate, demonstrating the value in providing a holistic approach to care. Nurses at the bedside play a crucial role in recognizing family coping strategies, identifying unmet family needs, and bridging gaps in communication.[7] Consultations with subspecialists in palliative care and ethics should be considered early in the course of hospitalization to improve communication, prevent conflict, identify important goals through eliciting patient values and preferences, and ultimately optimize shared medical decision making.[5] Physical therapy, occupational therapy, and rehabilitation medicine should be incorporated into the patient's care using a systematic approach to assist with functional recovery and potentially improve long-term quality of life. Specialists in music, art, and pet therapy; psychology; child life; and educational services can improve the quality of life in the ICU and reduce ICU-related morbidities, such as anxiety, depression, delirium, psychosis, and posttraumatic stress disorder.[4,7] Social workers can provide assistance to reduce both emotional distress and stressors that arise from practical aspects of having a child hospitalized, such as food, transportation, and employment, while chaplains can address the spiritual needs of the patient and family.[5,12,44] With the multitude of providers involved, excellent communication is necessary, as different messages can contribute additional stress to families.

In addition to incorporating health care providers from multiple disciplines, peer-to-peer support can also be highly beneficial.[1] Families may choose to serve on patient advocacy committees, share their experiences with other families through family support groups, and volunteer to serve as consultants to other families who are affected by similar disease processes or experiences. Allowing families who are in a crisis mode to contact and access other families who have shared similar experiences may broaden coping mechanisms and may help guide families through their journey, particularly when they are faced with making difficult decisions.

Collaborating and Building Partnerships With Patients and Families

Developing a partnership with families is essential to fulfilling the fundamental principles of PFCC. A partnership requires an "interpersonal relationship between two or more people who work together to achieve a mutually defined purpose," which, in the PICU, is, "providing the best possible care for the child from a holistic perspective."[45] The holistic approach requires inclusion of the family, as the center of strength for the child. When partnering with parents and caregivers who know the child best and provide invaluable information regarding who the child is as a person, health care providers treat the child more effectively and address the needs more appropriately.[45] This partnership, when developed effectively, allows parents and health care providers to contribute their own expertise to achieve a common goal, leading to a relationship in which the power differential between health care providers and families is diminished.[10]

Although building a partnership with patients and families at the bedside is essential, optimizing PFCC also requires collaboration, "at all levels of health care: in the delivery of care to the individual child; in professional education, policy making,

program development, implementation, and evaluation; and in health care facility design."[1] Encouraging families to participate in all the dimensions of health care through serving on family advisory councils, quality improvement projects, and developing research protocols is critical.[1] Furthermore, building this partnership requires a transdisciplinary approach and is "grounded in collaboration among patients, families, physicians, nurses, and other professionals in clinical care."[1] In order to optimize these relationships, clarity and transparency regarding the roles, boundaries, and expertise of each stakeholder are critical.

Empowering Patients and Families to Facilitate Shared Medical Decision Making

PFCC is optimized through "recognizing and building on the strengths of individual children and families and empowering them to discover their own strengths, build confidence, and participate in making choices and decisions about their health care."[1] Empowering the patient and family to participate in shared decision making is fundamental because "the perspectives and information provided by families, children, and young adults are essential components of high-quality clinical decision making."[1] In the ICU setting, complex and high-stakes decisions are made in a short time frame. In many circumstances, there is a high degree of uncertainty in outcomes, making these decisions even more difficult. The majority of these clinical decisions are based on the medical expertise, empirical evidence, experience of the health care providers and consultants, and most importantly, the values and perspectives of the patient and family.

By definition, shared decision making occurs when the physician, patient (if possible), and family "share their opinions and jointly reach a decision."[35] Dimensions of shared decision making include (1) providing medical information and eliciting patient values, preferences, and goals; (2) exploring the family's preferred role in decision making; and (3) deliberation and decision making.[35,46] Collaborative communication, as discussed earlier in this chapter, is required to adequately fulfill the first dimension. In regards to dimension 2, multiple studies demonstrate that families have varying decision-making preferences, particularly regarding limitation of life support or other aggressive interventions.[5,35] Therefore before making assumptions, exploring the family's preferential role in decision making is important. Furthermore, shared decision making should not be interpreted as allowing the family to decide without support from the providers, or giving families increased responsibility or autonomy, as, "there is a fine balance between supporting and guiding a family while allowing the family appropriate space to make their own decisions."[11,22] Most families do not want to feel alone when making difficult decisions. Recommendations and guidance from providers may help alleviate potential burdens associated with making difficult decisions. Finally, shared decision making does not mean that families should exclusively drive medical care or be empowered to make decisions that are not medically sound. The key aspect of shared decision making is that the process is collaborative and incorporates the opinions and expertise of all stakeholders. "Finding the right balance" among stakeholders to achieve "goal-oriented patient care" through established frameworks for shared decision making is necessary to provide optimal PFCC.[46]

There are multiple benefits associated with shared decision making. When patients and families become active participants in their health care, there is improved understanding and more motivation to follow through with care. In addition, for parents and caregivers who lose their sense of control with the hospitalization of a critically ill child, participating in decisions can provide a great source of strength. As one mother explains, "I was able to still be her mom."[47] By "encouraging them to continue actively in their parental role by promoting shared decision making and helping the family to retain their responsibilities throughout hospitalization," parents and caregivers retain their identities, which fosters the integrity of the parent-child relationship, maintains cultural and family traditions, and demonstrates respect for and value of the child as a person.[45,47] Although further studies are necessary to elucidate the important driving factors for parental decision making, parents overall want to be "good parents."[48] Understanding what parents value as important factors in "being a good parent" potentially may improve the quality of PFCC.[48]

Patient- and Family-Centered Care Improves Outcomes for All Stakeholders

Over the past 2 decades, PFCC has improved outcomes in the provision of high-quality patient care. According to the AAP, "patient- and family-centered care can improve patient and family outcomes, improve the patient's and family's experience, increase patient and family satisfaction, build on child and family strengths, increase professional satisfaction, decrease health care costs, and lead to more effective use of healthcare resources."[1]

According to numerous studies, patients and families directly benefit from the incorporation of the fundamental principles into practice. Patients and families have reduced anxiety, better cooperation, improved satisfaction, reduced emotional distress, better adjustment to hospitalization, and faster recovery from illness and surgery.[1,8] Because the needs of families are addressed more explicitly, families also have improved functioning, increased confidence in providing ongoing care to their child, greater willingness to seek help from health care providers, a greater degree of trust, and improved competence in problem-solving and making complicated health care decisions.[1,8] When families receive clear and consistent communication and actively participate in the care of their child, they experience a greater sense of control, resulting in preservation of the parent-child relationship, with reduced anxiety, posttraumatic stress, and complicated grief.[8]

Health care providers, institutions, and the health care systems also directly benefit from PFCC. When health care providers gain important insights into the needs and values of patients and their families, they establish trusting relationships and improve the quality, efficiency, and safety of the care they provide. As a result, providers have improved work satisfaction, which leads to improved job performance, reduced burnout, and decreased staff turnover.[1] With the provision of higher-quality care, health care institutions and systems benefit with reduced health care costs, improved patient and family satisfaction, and reduced risk for litigation, and they potentially gain a more competitive position in the marketplace.[1]

Overcoming Barriers and Challenges to Patient- and Family-Centered Care in the ICU

Although significant progress has been made in incorporating PFCC into the ICU, there remains a gap between current and proposed practice. Ongoing research reveals that families continue to express that their needs are not always met.[2,8,14,16,21] The reasons for this gap in practice are likely multifactorial, but several barriers are extremely challenging to overcome (Box 13.2). First, there is a fundamental difference in perceiving the ICU as a "bedroom" versus an "office."[21] For families, the ICU needs to serve as a "bedroom," where a sick child can experience warmth, comfort, and a healing environment. On the other hand, critical care providers need an "office" equipped with computers, monitors, alarms, and advanced technology. This dichotomy fundamentally inhibits the creation of a "bedroom" and reinforces the role of "the visitor" and "the patient" rather than fostering a collaborative partnership.[21] Second, the emotional intensity of the life-altering and life-threatening circumstances is unavoidable. The impact of this emotional intensity on patients and families, requiring extensive coping mechanisms, and the complexity of the medical care provided creates an implicit power differential among health care providers, patients, and families, furthermore reducing the ability to develop a partnership. Finally, the necessity to make high-stakes decisions wrought with uncertainty exposes fundamental differences in belief and value systems that are potentially challenging to overcome. Even under ideal circumstances with the most advanced communication systems and extensive training in cultural humility, these differences can create intense barriers and conflict, rooted in different perceptions of what is in the best interest of the patient, further impeding the development of partnership. Overcoming these fundamental barriers requires acknowledgement, transparency, and further research to identify both the explicit and implicit practices and values within the ICU[21] (Box 13.3). Using a model of PFCC, this research requires using a collaborative approach in which all stakeholders have an equal voice in order to develop creative solutions.

Box 13.2

Potential Barriers to Patient- and Family-Centered Care in the ICU

- Dichotomy in patient, family, and provider needs of the ICU as a "bedroom" versus an "office"
- Emotional intensity of life-altering and life-threatening circumstances
- High-stakes nature and complexity of medical decision making, requiring explicit value-based decisions
- Implicit and explicit power differential among health care providers, patients, and families
- Exaggeration of cultural and language barriers in the fast-paced, emotionally

intense, and complex setting

- Health care provider misperception of increased risk for litigation, distraction, and the inability to teach trainees with greater family involvement
- Increased complexity of patient population, lending to medically and technologically savvy families who have different needs and potentially require different models of care

Box 13.3

Overcoming Barriers to Patient- and Family-Centered Care in the ICU

- Provide formal training in cultural humility; develop a robust interpreter service and hire cultural navigators
- Provide formal training in collaborative communication and goal-oriented, shared medical decision making
- Include patient and family input for ICU policies, procedures, planning, and delivery of health care
- Acknowledge and maintain transparency regarding implicit and explicit values and practices in the ICU
- Support and engage in patient- and family-centered care research to identify and overcome additional barriers
- Develop adequate support systems for health care providers who suffer from compassion fatigue and vicarious trauma

In addition to these fundamental barriers, the patient population that requires pediatric intensive care is increasingly complex. Accommodating the needs of parents of medically complicated children who are medically and technologically savvy may require different models of care.[49] PICUs need to be able to fully accommodate the "skills and expertise" of families of chronically ill and medically complex patients, and "there is a clear need for research that identifies what constitutes success to these families, along with the challenges faced by staff who care for them … [in order to] change practice and foster a culture of supportive care inside the PICU."[49] PFCC is not equivalent to family-driven care, in which families exclusively direct the medical care, dominating the relationship. The establishment of professional boundaries and specific roles is critical in the development of mutually respectful and collaborative partnerships.

Finally, the development of compassion fatigue and secondary traumatization experienced by health care providers who are witnesses to extreme suffering of children and families in this complex environment can also lead to disengagement from patients and families.[50] High clinical workloads and demanding extraneous professional obligations can lead to provider burnout and the loss of the ability to

maintain an empathetic approach to patients and families. Therefore the needs of health care providers also should be explicitly recognized and addressed by institutions and health care systems in order to improve the quality of PFCC delivered.

Summary

The pediatric critical care unit is a complex environment that creates a high level of stress for patients and families. Incorporating PFCC into practice improves patient and family satisfaction, reduces stress and anxiety, fosters the parent-child relationship, and ultimately increases the quality, efficacy, efficiency, and safety of care delivered. Developing a partnership with patients and families built on mutual respect, using collaborative communication, providing extensive support for the family unit, and encouraging patient and family participation in all aspects of care, including shared medical decision making, are fundamental principles essential to the practice of patient- and family-centered care. Overcoming real and perceived barriers to incorporating PFCC into practice requires a collaborative and transparent approach involving all stakeholders to identify creative solutions, while providing adequate support to health providers who are at risk for compassion fatigue, secondary traumatization, and burnout.

CHAPTER 14

Ethics in Pediatric Intensive Care

Mithya Lewis-Newby, Douglas S. Diekema

PEARLS

- Ethical issues in the pediatric intensive care unit (PICU) include high-visibility crises, as well as subtle everyday ethical issues that stem from values and biases that infuse daily decisions.
- Critical care clinicians should develop an approach to ethical issues that includes (1) recognition and clarification, (2) information gathering, (3) ethical analysis, (4) communication of recommendations, and (5) support of the patient, family, and medical team.
- Autonomy to make choices in medical decisions is embodied in the requirements of the Doctrine of Informed Consent: disclosure, understanding, competency, and voluntariness.
- Adolescents designated as emancipated or mature minors may be considered competent to make independent medical decisions. Clinicians should strongly consider including adolescents in medical decisions even if they do not possess the legal right to do so.
- Surrogate decision making is common in the PICU. For previously competent patients, surrogates should make decisions consistent with the patient's previously expressed values ("substituted judgment standard"). For patients who have not previously been competent, surrogates must decide what is in the best interest of the patient from the patient's perspective ("best interest standard").
- Except in emergencies, clinicians must obtain legal permission to override parental refusals of recommended medical services. Clinicians must establish that the intervention will benefit the child and that forgoing the intervention places the child at significant risk of serious harm. Mediation and negotiation toward finding a mutually acceptable solution should be attempted before seeking legal intervention.
- Disputes regarding potentially inappropriate or "futile" services in cases where there is a lack of consensus about what constitutes accepted medical practice should be resolved through a fair process-based approach.

Defining Bioethics

"Bioethics is the discipline devoted to the identification, analysis, and resolution of value-based problems and competing moral claims that arise in medicine between patients, families, healthcare professionals, healthcare institutions, and society at large."[1]

Examples of Ethical Issues in the PICU

Critical care clinicians (including physicians, nurses, respiratory therapists, and other staff) face issues every day in the practice of pediatric critical care medicine. Some ethical issues occur daily (everyday ethics) in the pediatric intensive care unit (PICU) but may be subtle and difficult to recognize, such as how rounds are prioritized or how implicit biases are infused into clinician communication and decision making. Other ethical issues, such as a heated disagreement between the medical team and a family about the best course of action for a critically ill child (crisis ethics), are typically more obvious to everyone involved. The following are examples of ethical issues that may arise in the PICU:

- Prioritizing rounds to address the sickest first (prioritarianism and scarce resource allocation)
- Advising a family to withdraw life-sustaining therapies in the setting of a severe brain injury (value-based judgment)
- Transfusing a hemorrhaging child against the wishes of his parents who are of the Jehovah's Witness faith (best interest standard and harm principle)
- Treating an air-hungry dying child with morphine to the point of unconsciousness and bradypnea (doctrine of double effect)
- Lifting sedation on an 18-year-old on extracorporeal membrane oxygenation (ECMO) to discuss the possible limitation of life support (doctrine of informed consent)

Domains of Bioethics

The practice of bioethics encompasses many different domains. These domains may be present to varying degrees in individual ethical issues.

Value-Based Decision Making

In pluralistic societies (such as the United States) where moral diversity is prevalent, individuals or groups may have competing or conflicting moral claims. These moral claims are based on differing values that are not easily compared. For example, some individuals may place great value on the extension of life even if it entails significant burdens, whereas other individuals may value the quality of life more highly than life extension. The clinician should make every effort to identify and understand the moral values that underlie the positions of different stakeholders.

State and National Laws and Legal Precedence

The law interacts frequently with bioethics in several important ways. First, the answer to many questions that are framed as ethical issues is based on the law (eg,

age of competency for decision making). Second, at times legal action may be required for the resolution of ethical issues (eg, a court-appointed decision maker may be required in certain cases of medical neglect). Finally, legal precedent may help inform analogous bioethics cases (eg, previous cases regarding emergent blood transfusions or the prolongation or withdrawal of life support).

Professional Codes and Health Care Organization Policies and Regulations

Most medical disciplines adhere to a professional "code of ethics."[1,2] These codes should be considered in ethical analysis. Additionally, health care organizations issue various policies around ethics (eg, allocation of resources, conscientious objection, or disclosure of medical error) with which the ethicist and clinician must be familiar. Finally, national health care organizations such as Medicaid and Medicare, as well as insurance companies, may have regulations that impact ethical practice (such as the Centers for Medicare and Medicaid Services [CMS] requirement that all patients older than 18 be asked about an advanced directive on admission to the hospital).

Communication, Negotiation, and Mediation

A large portion of ethical issues stems from communication that has broken down. In many cases, what may seem like an intractable dispute can be resolved by repairing communication between parties. Resolving some communication problems may be facilitated by the ethicist, a role in which expert conflict mediation skills prove valuable. For example, staff distress may be addressed with a staff-only meeting to better understand the roots of the distress and allow a venue in which differences of opinion can be aired. Another example includes a family who feels that their goals are unheard or misunderstood and who may benefit from a series of facilitated care conferences with the medical team at which a common understanding of the situation and goals of care might be achieved.

Prevailing Ethical Theories and Norms

Certainly, the ethicist should be knowledgeable about prevailing ethical theories and norms and adept at applying them to bioethical dilemmas (see later section for more details about specific ethical theories). There is no overarching ethical theory that can resolve all ethical dilemmas. Instead, ethical dilemmas are often examined under the lens of several theories in order to come to a "best possible" recommendation. It is important to recognize that these ethical theories and norms are not static, and that they are society and culture dependent.

Who Should Address Ethical Issues in the PICU?

A wide variety of ethical issues arise in the PICU. Different ethical issues may require different levels of analysis and resolution. Some issues may be resolved with relatively basic skills, while the resolution of other issues may require significantly advanced skills. Some ethical issues may be resolved easily and quickly by the critical care clinician, others may require the advanced skills of an ethics consultant, and others may require review by a multimember ethics committee.

Critical Care Team

Many ethical issues can and should be addressed by the intensivist or the PICU team. Just as pediatric intensivists are trained to provide primary cardiology, neurology, nephrology, palliative, and other specialized care with subspecialty consultation in complex cases, the same should be true for bioethics. All pediatric intensivists should be trained in and pursue continuing education in bioethics. Ethical issues are common in the PICU, and all intensivists should have a solid understanding of the basic aspects involved in identifying, analyzing, and resolving bioethical dilemmas. This will require an understanding of the basics of the domains mentioned earlier, as well as comfort with a basic tool set for approaching ethical issues. Routinely addressing basic ethical issues may resolve simpler bioethical issues quickly, help in deescalating more complex conflicts before they become intractable, and in some cases prevent issues from arising in the first place.

Ethics Consultant

For more complex bioethical dilemmas, pediatric bioethics specialists may be consulted. Ethicists come from a variety of disciplines, training, and experiences. Ethics consultants should have advanced skills in ethical assessment and analysis, ethical and hospital processes, and interpersonal skills in negotiation, communication, and facilitation. Additionally, ethics consultants should be experienced in advanced moral reasoning and ethical theory, be facile with advanced bioethical concepts, and have a strong knowledge base about how health care systems, clinical context, institutional policies, and health law impact ethical decisions.[3] The *pediatric* bioethics consultant should additionally be knowledgeable about the unique ethical issues that arise in the pediatric setting.

Ethics Committee

Some ethical issues may require resolution or final recommendation from a full ethics committee, composed of members from a wide variety of disciplines and representing a diverse set of values, experiences, and perspectives. Ideally, ethics committees should promote a fair process and reduce the risk of arbitrariness.[3,4] Examples of issues that are optimal for an ethics committee review include cases involving an intractable conflict of values, potentially high-visibility cases, and institutional ethics issues. Ethics committees may also perform post-hoc review of cases handled by ethics consultants for purposes of quality improvement.

Approach to Bioethics Dilemmas in the PICU

Critical care clinicians should learn and become competent with a basic organized analytic approach to ethical dilemmas. Several approaches have been published, and most contain the same basic elements.[5-7] In general, a systematic approach to ethical issues will involve five elements: recognition and clarification, information gathering, analysis of issues, communication of recommendations, and support (Fig. 14.1, Tables 14.1 and 14.2).

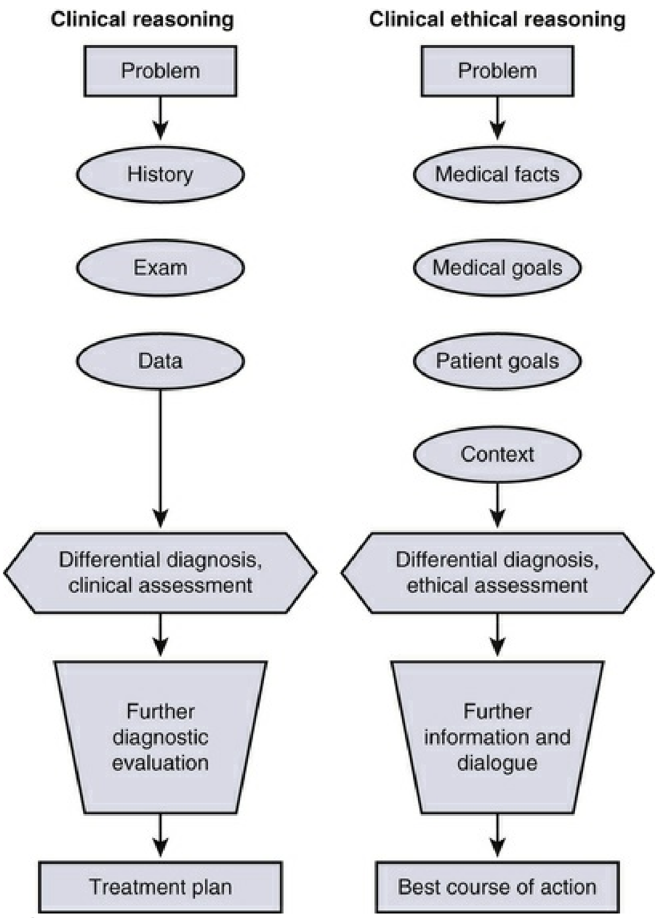

FIG. 14.1 Comparison between clinical reasoning and clinical ethical reasoning. (From Kaldjian L, Weir R, Duffy T. A clinician's approach to clinical ethical reasoning. J Gen Intern Med. 2005;20:306-311.)

TABLE 14.1
CASES–A Step-by-Step Approach to Ethics Consultation

C	CLARIFY THE CONSULTATION REQUEST • Characterize the type of consultation request • Obtain preliminary information from the requester • Establish realistic expectations about the consultation process • Formulate the ethics questions
A	ASSEMBLE THE RELEVANT INFORMATION • Consider the types of information needed • Identify the appropriate sources of information • Gather information systematically from each source • Summarize the case and the ethics questions
S	SYNTHESIZE THE INFORMATION • Determine whether a formal meeting is needed • Engage in ethical analysis • Identify the ethically appropriate decision maker • Facilitate moral deliberation about ethically justifiable options
E	EXPLAIN THE SYNTHESIS • Communicate the synthesis to key participants • Provide additional resources • Document the consultation in the health record • Document the consultation in consultation service records
S	SUPPORT THE CONSULTATION PROCESS • Follow up with participants • Evaluate the consultation • Adjust the consultation process • Identify underlying systems issues

TABLE 14.2

A Case-Based Approach to Ethical Decision Making

MEDICAL INDICATIONS Principles of Beneficence and Nonmaleficence 1. What is the patient's medical problem? Is the problem acute? Chronic? Critical? Reversible? Emergent? Terminal? 2. What are the goals of treatment? 3. In what circumstances are medical treatments not indicated? 4. What are the probabilities of success of various treatment options? 5. In sum, how can this patient be benefited by medical and nursing care, and how can harm be avoided?	PATIENT PREFERENCES Principles of Respect for Autonomy 1. Has the patient been informed of benefits and risks, understood this information, and given consent? 2. Is the patient mentally capable and legally competent, and is there evidence of incapacity? 3. If mentally capable, what preferences about treatment is the patient stating? 4. If incapacitated, has the patient expressed prior preferences? 5. Who is the appropriate surrogate to make decisions for the incapacitated patient? 6. Is the patient unwilling or unable to cooperate with medical treatment? If so, why?
QUALITY OF LIFE Principles of Beneficence, Nonmaleficence, and Respect for Autonomy 1. What are the prospects, with or without treatment, for a return to normal life, and what physical, mental, and social deficits might the patient experience even if treatment succeeds? 2. On what grounds can anyone judge that some quality of life would be undesirable for a patient who cannot make or express such a judgment? 3. Are there biases that might prejudice the provider's evaluation of the patient's quality of life? 4. What ethical issues arise concerning improving or enhancing a patient's quality of life? 5. Do quality-of-life assessments raise any questions regarding changes in treatment plans, such as forgoing life-sustaining treatment? 6. What are the plans and rationale to forgo life-sustaining treatment? 7. What is the legal and ethical status of suicide?	CONTEXTUAL FEATURES Principles of Justice and Fairness 1. Are there professional, interprofessional, or business interests that might create conflicts of interest in the clinical treatment of patients? 2. Are there parties other than clinicians and patients, such as family members, who have an interest in clinical decisions? 3. What are the limits imposed on patient confidentiality by the legitimate interests of third parties? 4. Are there financial factors that create conflicts of interest in clinical decisions? 5. Are there problems of allocation of scarce health resources that might affect clinical decisions? 6. Are there religious issues that might affect clinical decisions? 7. What are the legal issues that might affect clinical decisions? 8. Are there considerations of clinical research and education that might affect clinical decisions? 9. Are there issues of public health and safety that affect clinical decisions? 10. Are there conflicts of interest within institutions or organizations (eg, hospitals) that may affect clinical decisions and patient welfare?

Adapted from Jonsen AR, Siegler M, Winslade W. Clinical Ethics. 7th ed. New York, NY: McGraw-Hill; 2010. https://depts.washington.edu/bioethx/tools/4boxes.html.

Recognition and Clarification of Ethical Issues

The first step in approaching any ethical issue is to recognize that the situation raises a question related to ethics. Some issues may be more appropriately handled by a child protection team (when neglect or abuse is obviously the issue) or a palliative care team (when there is no conflict over the appropriateness of palliative care but help is required in transitioning to a palliative care plan) (see also Chapter 16). During this first stage, it is also appropriate to assess and optimize communication. Communication that has broken down is frequently a contributor, if not the basis of ethical disputes. At a minimum, improving communication commonly will help to diffuse a crisis so that the issue can be addressed productively. At times, improved

communication between parties may be sufficient to resolve the issue all together. Finally, once an ethical issue has been identified, the next step is to try to articulate, as precisely as possible, the nature of the ethical question.

Information Gathering

"Good ethics requires good facts" is a common saying in bioethics circles. Sound bioethical recommendations can only arise from a solid understanding of the facts involved in the case. Facts include medical facts, such as the mortality rate for a procedure or condition both at the institution and nationally, alternate medical options, or an accurate assessment of the child's medical condition. Facts also include relevant contextual details such as family culture and religion, family circumstances, available resources and support, etc. A useful tool for gathering facts surrounding an ethical issue is the "four categories" method (Table 14.2).[7]

During this phase, it is important to seek to understand the perspectives, values, and goals of the patient (if possible), the family or other surrogates, and various involved members of the medical team (including primary physicians, consulting physicians, nurses, and other staff). When possible, these perspectives should be obtained firsthand to avoid the inevitable misunderstandings that result from second- or third-hand information. It is important to understand stakeholders' opinions, but also the goals and values behind their opinions. Often, a better understanding of the stakeholders' underlying values and deeper goals can help to clarify stated requests and open a path to resolution.

Finally, identifying or refining the core ethical dilemma or primary conflict may be easier once the appropriate data have been collected and the voices of those with a stake in the situation have been heard. It is an important skill and part of the assessment to be able to identify and clarify the ethical dimensions to the dilemma.

Analysis of Ethical Issues

Once the ethical question has been clarified, the facts have been gathered, and the voices of the stakeholders heard, the next step is to begin an ethical analysis of the case. Relevant institutional policies, health care regulations, and legal standards should be applied to the case.

In value-based ethical dilemmas a variety of ethical theories may be applied to assist in determining the recommended course of action. It is important to understand that there is no consensus about a predominant ethical theory. All ethical theories have benefits and limitations. They can and should be used in combination to help analyze the situation and assist in coming to the "best possible" set of recommendations. The following is a limited example of ethical theories that may be applied to the analysis of ethical dilemmas:

Consequentialism

A consequentialist approach to moral decisions will focus primarily on the predicted outcomes of various choices. Of reasonable options available, the best choice will be the one most likely to provide the most favorable balance of benefit versus burden. Generally in bedside decision making, a consequentialist approach is based in the principle of beneficence, focusing the analysis on the benefits and burdens *to the*

patient.[8]

Deontology

A deontologic approach to moral decisions will focus on moral duties, rights of others, and ethical rules and principles, regardless of the ultimate outcome of the decision. A deontologist might, for example, insist on the application of a rule to always tell the truth, rather than attempting to assess whether telling the truth would result in a good or a bad outcome.

Principalism

Most medical ethicists agree on a small number of principles that should generally guide medical behavior. These include respect for autonomy, beneficence, nonmaleficence, and justice. The principle of ***respect for autonomy*** places the desires and decisions of the competent patient as the most important consideration in deciding on a course of action. Because individual values about benefits and harms differ, individual wishes should be respected, and the clinician's primary duty is to assure that the patient has the information required to make a decision and understands that information. Some have argued for a broader principle of respect for persons, on the basis that there are ways of respecting persons that are important even for nonautonomous individuals (like children). The principle of ***beneficence*** requires that clinicians take positive steps to help their patients, and medical interventions should ultimately benefit the patient. This principle demands that the primary consideration in all therapeutic decisions be the good of the patient. Closely related to the principle of beneficence is the principle of nonmaleficence. ***Nonmaleficence*** holds that clinicians have a duty to avoid causing unnecessary harm to patients. In the PICU, many medical therapies (such as intubation) inadvertently cause suffering or are burdensome, and the principle of nonmaleficence requires that the benefit of these procedures justify the harm, burden, or suffering that may occur as a result of their use. The ***principle of double effect*** (see Chapter 15 for further details) is sometimes used in determining whether an action that causes both benefit and harm can be justified. At its core, this principle requires that clinicians always consider the suffering of the patient when making medical recommendations. Finally, the principle of ***justice*** is a complicated principle that seeks fairness when competing claims exist. Among other things, the principle requires that scarce resources be distributed fairly and not based on irrelevant factors. One limitation of principalism is that it lacks guidance about how to prioritize these principles when they are in conflict with one another in an individual case.[9]

Virtue-Based Ethics

Virtue-based theories of ethics emphasize the moral character of the individual clinician. In other words, the clinician who possesses desirable, virtuous characteristics is more likely to make the best ethical choice most consistently. Virtue-based approaches tend to be most helpful when addressing boundary issues, conscientious objection, or other issues related to professionalism and are often less helpful in the more typical conflicts that occur in the patient care setting.

Casuistic Ethics

A casuistic approach to ethical issues analyzes the current ethical issue by comparing it with prior similar cases and others' past experiences and previous outcomes to help determine the best decision. It is similar to the reasoning used in legal cases, where key precedential cases may be used as “anchors” for appropriate resolutions. The analysis then seeks to explore similarities and differences between the current situation and those precedential cases in determining whether similar or different resolutions would be most appropriate.

Care Ethics

Ethics of care shifts the moral question from “what is just?” to “how should we respond?” Instead of basing decisions on universal standards and impartiality, the ethics of care argues that caring for others and preserving relationships are the foundations of morality.

Narrative Ethics

Narrative approaches to ethical issues emphasize the importance of understanding cases in all of their details and complexities and seek to avoid reducing cases to essential elements and then applying a rule or principle. In this approach, details matter and the resolution of a specific situation may be determined by how each of the possible options will best fit the narrative of the patient's life (or death).

During the process of ethical analysis and consideration of recommendations, it may be helpful to consider whether a solution exists that has not yet been considered by the different stakeholders. Initially, in a conflict, stakeholders may strongly advocate for their specific requests. Through a thorough examination of the case, optimization of communication, and a deeper understanding of the underlying goals and values of the stakeholders, an alternative solution that may satisfy all of the stakeholders, at least to some degree, may become apparent. Clinical ethicists should always seek to identify these alternate, often creative, solutions.

Communication of Recommendations

Once an ethical analysis has occurred, the resulting recommendations must be communicated to the parties with a stake in the outcome. This may include a note or notes in the patient's chart and may involve discussions with the patient, family, and staff involved in the care of the patient. Care should be taken to fully and transparently disclose the rationale behind the recommendations. Stakeholders should have the opportunity for appeal, a process that may be facilitated by the ethics committee, a patient advocate, or some other institutional mechanism. Importantly, the recommendations of ethics consultants and committees are just that—recommendations to the clinical team. Support for the recommendations and ultimate decision making may require hospital administration or even the courts in some cases.

Support

Even after a decision has been made about how to proceed, patients, families, and staff often require additional support.

Address Staff Distress

Medical staff distress is often an important component of ethical issues. Staff may experience moral distress from continuing or not pursuing a particular plan for a patient. Addressing staff distress through individual conversations or staff-only meetings may help to deescalate the conflict. Failure to address staff distress may contribute to burnout, job dissatisfaction, and compassion fatigue.[10]

Support the Patient and Family

Patients and families involved in an ethical dilemma are often under a tremendous amount of stress. This is in addition to the stresses that result simply from having a child admitted to the PICU. Families may perceive a lack of power and support in the PICU environment and even the ethics consultants and committees may be seen as part of the power structure of the hospital. It is important to identify advocates and support mechanisms for patients and families under these conditions (see also Chapter 13).

Ethics of Patient and Surrogate Decision Making

Although the concept of patient autonomy seems obvious to all who practice medicine in this era, it was only a little over 60 years ago when the trend was for doctors to be more paternalistic and directive about medical decisions and for patients to accept these decisions. In the 1960s, a patient movement began to advocate for more patient autonomy in decision making. In that era, the predominant ethical cases surrounded the right to die. A landmark case in 1975 involved Karen Ann Quinlan, whose parents wanted the right to remove the ventilator from their daughter who was in a persistent vegetative state. The physicians refused, believing they would be killing her and fearful of homicide charges. The beginning of the patient autonomy movement was focused on the right to *refuse* treatments. Generally speaking, these trends toward autonomy and personal choice became embodied in the ***doctrine of informed consent.*** Over the past several decades the pendulum has continued to shift beyond "right to die" cases. More recent trends in the patient autonomy movement surround the "right to live" and "right to demand treatments."

Patient Decision Making

Patients are given a tremendous amount of latitude to accept or refuse offered medical treatments if the patient is deemed competent for decision making.

Doctrine of Informed Consent

The doctrine of informed consent applies to both medical decisions and research. Informed consent must satisfy four requirements that apply when surrogates provide permission, as well as when consent is obtained directly from patients. *Disclosure* means the clinician should supply the patient with sufficient information that a "reasonable person" would desire to be able to make an informed medical

decision. *Understanding* means the clinician should assess the patient's understanding of the proposed course of action, the risks and benefits of that course of action, and any available alternatives along with the risks and benefits associated with those. Understanding may be particularly impaired in the critical care setting, where the high stakes and time pressures can impact the ability to achieve optimal understanding. *Capacity* means the patient must meet legal requirements for competency, be able to understand the medical decision, form a reasonable judgment based on the consequences of the decision, and be able to communicate that decision to others. Legally, children younger than the age of 18 are not considered competent for medical decision making with the exception of emancipated and mature minors. *Emancipated minors* are considered competent on the basis of characteristics that are defined by state law but which may include pregnancy, parenthood, or establishing financial independence. *Mature minors* represent another category that is defined by state law whereby a minor, usually above a certain age, can be judged competent to make certain medical decisions. Most states require a judge to make these determinations, and the judge may restrict the determination to the medical decisions at hand. *Voluntariness* means decisions must be voluntary and not subject to coercion, manipulation, or undue influence. Importantly, physicians should not withhold or deemphasize information in an effort to manipulate patients.[11]

Emergency Exception to Informed Consent

Under specific emergent circumstances, informed consent may be forgone in order to provide necessary lifesaving medical interventions. The emergency exception requires that the medical care in question is required emergently, the patient is incompetent, that no surrogates are readily available, and that medical intervention is needed to save the patient's life or prevent permanent disability.

Advance Directives

Advanced directives allow formerly competent patients to document their values and medical decision-making preferences ahead of time.[12] *Living wills* document values and desires in writing, and *health care durable power of attorney* designates a surrogate who presumably understands the patient's values and desires. The Patient Self-Determination Act requires all Medicare/Medicaid participating institutions to inform patients older than the age of 18 of their rights to formulate advance directives on admission. Advanced directives for children can also be developed by parents or other guardians with input from children as appropriate.[13]

Child and Adolescent Decision Making

Children younger than the age of 18 are generally considered not competent to make medical decisions unless they meet criteria for emancipation or mature minor status. However, most agree that the opinions of children and adolescents should not simply be disregarded. Adolescents should be involved in discussions about their health care and should be offered the opportunity to voice their feelings, opinions, and concerns, and they should be provided reasonable opportunities to make choices and have those choices respected.[14] On the other hand, there is no consensus as to whether any adolescent is truly mature enough to refuse lifesaving treatment in

situations where there is likely to be a good prognosis with a proven intervention. Although adolescents older than the age of 13 are generally capable of making rational decisions, they are less likely to do so under conditions of high emotion or intense pressure. They are more likely than adults to act impulsively without full consideration of consequences, and they tend to weigh current rewards and harms more strongly than future consequences of a decision.

Many factors would be relevant in determining whether an adolescent possesses sufficient maturity to make a life-altering medical decision. Minimally, however, judges and clinicians should require a high level of psychosocial maturity and consider the adolescent's ability to understand and reason, project meaningfully into the future, express a relatively settled set of values and beliefs, and demonstrate that his or her decision is driven more by long-term interests than short-term concerns. The chances of a good outcome with treatment and the burden of the proposed interventions are also relevant considerations. In general, it would be unusual to allow an adolescent to refuse interventions in a situation where the parents would not be allowed to make that decision for him or her.[15]

Shared Decision Making

The patient autonomy movement that began in the 1960s moved us away from a predominantly paternalistic approach. There has been some concern that the pendulum has swung too far and that patients are all too frequently provided with a menu of options without sufficient guidance in decision making. The middle ground is shared decision making. Shared decision making should combine the clinician's expert knowledge and experience with the patient's values and preferences. Even though patients are rightfully granted autonomy to give informed consent, clinicians should not abdicate responsibility for recommending a course of action and guiding the patient through the decision-making process (see Chapter 13 for additional discussion).

Surrogate Decision Making

In critical care medicine (adult and pediatric), it is not uncommon for patients to lack decision-making capacity. In these situations, a surrogate decision maker is required to participate in medical decision making. Surrogate decision making falls into two categories: decision making for patients who were previously recognized as competent under the law (eg, a 22-year-old) and patients who have never been competent (eg, a 4-month-old). Surrogates must adhere to different standards in each of these two categories.

Surrogate Decision Making for Previously Competent Patients

In this category of the formerly competent patient, the surrogate decision maker (parent, spouse, etc.) must adhere to the *substituted judgment standard*. In other words, the surrogate is asked to make decisions most consistent with what the patient would have wanted. This is an attempt to preserve the patient's autonomy and honor the patient's values. There may be some cases in the PICU where this standard applies, such as older adolescents who have been living with chronic disease or young adults who have been admitted to the unit.

Surrogate Decision Making for Never-Competent Patients

In this category of the not previously competent patient (which includes the majority of patients in the PICU), surrogates are held to a different standard—that of the *best interest standard*. In theory, most children have not yet developed stable values and beliefs, and therefore these values cannot be known and cannot be used for surrogate decision making. The best interest standard attempts to maximize the benefit-to-burden ratio for the patient, from the patient's perspective. This, of course, is open to interpretation (and conflict) regarding how to calculate and weigh the various "benefits" and "burdens" as they would be experienced by the patient. "Quality of life" is a phrase that arises commonly in conversations about a patient's best interest. It is important to keep in mind that "quality of life" is a subjective and value-based assessment. Clinicians should be aware of their own biases, and caution should be used when applying this concept to the best interest standard.

Parents as Surrogate Decision Makers

Parents (or guardians) are generally empowered to make health care decisions on behalf of their children and, with few exceptions, have the legal authority to do so. From an ethical perspective, parents are generally considered the default surrogate decision makers for their children because they are most likely to understand the unique needs of each child and are presumed to desire what is best for the child. Additionally, some degree of family autonomy is considered an important social value. Finally, in settings of uncertainty, family values and competing family interests may be considered.

Limits of Parental Refusals

In most situations, parents are granted wide latitude in the decisions they make on behalf of their children, and the law has respected those decisions except when they place the child's health, well-being, or life in jeopardy.[16] Parental authority is not absolute, however, and when a parent or guardian fails to adequately guard the interests of a child, the decision may be challenged and the state may intervene. A clinician's authority to interfere with parental decision making is limited. Except in emergency situations where a child's life is threatened imminently, or a delay would result in significant suffering or risk to the child, the physician cannot do anything to a child without the permission of the child's parent or guardian. Touching (physical examination, diagnostic testing, or administering a medication) without consent is generally considered a battery under the law. The clinician's options include either tolerating the parents' decision (while continuing to try to convince them to act otherwise) or involving a state agency to assume medical decision-making authority on behalf of the child.

Only the state can order a parent to comply with medical recommendations. This can take different forms but most frequently either includes involvement of child protective services (under a claim of medical neglect) or a court order. Both of these represent a serious challenge to parental authority and will generally be perceived as disrespectful and adversarial by parents. Such action interferes with family autonomy, can adversely affect the family's future interactions with medical professionals, and can negatively impact the emotional well-being of the child. Neither should be undertaken without serious consideration. Before initiating

involvement of state agencies to limit parental authority and override parental refusal, the clinician must establish that (1) the recommended course of action is likely to benefit the child in an important way; (2) the treatment is of proven efficacy with a reasonable likelihood of success; (3) the parent or surrogate's decision to refuse intervention places the child at *significant* risk of *serious* harm in comparison with the recommendations of the health care team (applying the *harm principle*); and that (4) all attempts at mediation and negotiation to find a mutually acceptable solution have been exhausted (Box 14.1).[17]

Box 14.1

Conditions for Justified State Interference with Parental Decision Making

1. By refusing to consent, are the parents placing their child at significant risk of serious harm?
2. Is the harm imminent, requiring immediate action to prevent it?
3. Is the intervention that has been refused necessary to prevent the serious harm?
4. Is the intervention that has been refused of proven efficacy and therefore likely to prevent the harm?
5. Does the intervention that has been refused by the parents not also place the child at significant risk of serious harm, and do its projected benefits outweigh its projected burdens significantly more favorably than the option chosen by the parents?
6. Would any other option prevent serious harm to the child in a way that is less intrusive to parental autonomy and more acceptable to the parents?
7. Can the state intervention be generalized to all other situations?
8. Would most parents agree that the state intervention was reasonable?

Diekema DS. Parental refusals of medical treatment: the harm principle as threshold for state intervention. Theor Med Bioeth. 2004;25:243-264.

Limits of Parental Demands

There are also limits to a parent's ability to *demand* medical therapies that are not recommended by the medical team. Clinicians need not always accede to parental requests. Health care professionals have an independent obligation to apply their knowledge and skills in a way that meets professional standards of care and benefits the patient. For example, clinicians can refuse parental requests for medical therapies for their children that clearly are not medically indicated, such as antifungal medications for a bacterial pneumonia or an appendectomy for acute gastroenteritis.

There are other circumstances, however, when parents and the medical team have value-based disagreements about medical therapies. A classic example is that of

parents who demand ongoing mechanical ventilation for their child in a persistent vegetative state against the recommendation of the medical team. These cases involving requests or demands for potentially inappropriate or nonbeneficial treatments (previously known as "futility" cases) require special consideration primarily because it is difficult to prioritize conflicting values in our pluralistic society. To resolve these value-based disagreements, most major medical societies recommend the use of what is called a "fair process-based approach." Once again, optimizing early intrateam and team-family communication, as well as attempts at early conflict resolution, may prevent many of these cases from reaching a "crisis" level.[18] (For a complete discussion of this complicated topic, see Chapter 15.)

Other Ethical Issues in the PICU

Research Ethics

On the quest for continual improvement of the delivery of critical care, children admitted to the PICU are often participants in research. Clinicians should be familiar with the basic ethical and regulatory aspects of clinical research in children.[19,20] The doctrine of informed consent applies to most research. Child assent is generally required for research involving children unless an institutional review board (IRB) has waived the regulatory requirement for child assent because the child lacks the capacity for assent or the research offers a prospect of *direct* benefit to the child that is not available outside of the research. In healthy children, only research that poses no more than minimal risk to the child is acceptable. In children with disease, more than minimal risk may be acceptable only if there is a prospect of direct benefit to the individual child or if the research is likely to yield generalizable knowledge that is vital to understanding the child's condition *and* the research exposes the child to no more than a minor increase over minimal risk. All research requires approval of an IRB.

There are additional ethical considerations regarding research in the PICU. First, patients and families in the PICU are commonly under tremendous duress, are particularly vulnerable due to critical illness, and may have difficulty truly engaging in the informed consent process.[21] Second, PICU clinicians and researchers are often one and the same, and families may feel conflicted about declining research and may worry about how their lack of research participation may influence the clinical care their child receives. Researchers should be cautious to avoid undue influence or pressure on families when approaching them about enrollment in PICU research.

Resource Allocation

Resource allocation is pertinent in the PICU in two ways. Planning for disasters and other surges in the need for critical care requires careful consideration of how scarce resources will be allocated when demand exceeds resources. Additionally, one of the greatest ethical dilemmas facing our current generation is the need to control resource consumption and allocate health care resources in a sustainable way on a daily basis. As technology advances at breathtaking speeds, there is more and more we can do to prolong life. What is our individual or collective role in controlling the use of technology and practicing stewardship of our resources? National experts

have thus far been unable to come to consensus on an ethical approach to fairly allocate resources during disasters or how to consistently and fairly balance cost, quality of care, and quality of life in the critical care setting. Importantly, resource allocation policies should be addressed at the policy level, NOT at the bedside by individual clinicians. Individual institutions should have clear protocols about allocation of limited resources (eg, PICU beds, ventilators, ECMO circuits, diversion policies) that may occur during times of surge so that individual clinicians make triage decisions using the same standardized criteria in order to avoid variability as much as possible. ICU clinicians should engage at the institutional, regional, and national level to affect public policy regarding the allocation of resources. Finally, any resource allocation strategy should be developed with broad social input and should be transparent[22-25] (see also Chapter 24).

Ethical Issues at the End of Life

Many ethical dilemmas arise at the end of life. These issues, which include withdrawing and withholding life support, analgesia, and sedation at the end of life and the *doctrine of double effect,* definitions of death, and organ donation, are covered in other chapters (see also Chapters 15-17).

Limits to Clinician Refusals

Generally, clinicians have no legal duty to provide illegal therapies, therapies for which the physician is not qualified or competent to provide, therapies that are considered "unnecessary" or "nonindicated" (such as antifungals for a bacterial pneumonia), or any therapy that is disallowed by institutional or legal decision. However, clinicians may not refuse to provide accepted medical care to patients on the basis of invidious discrimination (eg, race, gender).

There is ongoing debate, however, about the extent to which a clinician can refuse to provide accepted medical care based on personal moral beliefs, also known as *conscientious objections*.[26,27] Generally, these types of refusals should only be accommodated if the refusal will not harm the patient and the refusal will not create undue burdens for colleagues or the institution. Providing a personal exemption under these circumstances typically requires that another clinician take over the care of the patient in a timely manner. Accommodation may not be possible in all cases; in such instances the clinician would be required to provide the service or face institutional or legal consequences.

Importantly, a conscientious objection is not sufficient justification for unilaterally forgoing life-sustaining therapies against the wishes of a patient or surrogates. A conscientious objection should only be used to request a personal exemption from providing a service (a shield), not to impose the clinician's moral values onto the patient (a sword). A fair process-based approach should be used to resolve such conflicts, as discussed previously.

Medical Training

Many PICUs are located within pediatric teaching hospitals. Nursing students, medical students and residents, and other professional trainees may rotate through

PICUs, learning valuable critical care medicine. There are also a fair number of PICUs nationally that have established pediatric critical care medicine fellowships, and these training programs are essential to continuing to train the next generation of pediatric intensivists. The balance of benefits to the trainee (and potentially patient and family) must be weighed against the potential risks and burdens to the patient and family from receiving care from an inexperienced clinician, particularly in the setting of a critically ill child. To mitigate the risks and burdens to the child and the family, other teaching methods (such as simulation) should be optimized, strict standards for supervision should be applied until competency is established, and the level of training should always be disclosed to the family[28] (see also Chapter 22).

Use of Unproven Medical Therapies

In the often dramatic and emotionally charged fight to save a child's life, the medical team may consider employing medical therapies that are new, have little to no evidence, or can be considered truly experimental outside of a conventional research setting. Typically, clinicians only consider these options when all other conventional options have failed and the outcome without them is near certain death. The potential benefits to using unproven medical therapies include prolonging the child's life, “pushing the envelope” for the development of new therapies and technologies over time, and adding to the fund of knowledge about the therapy. Because childhood critical illness is relatively rare, large randomized controlled trials may be unrealistic. On the other hand, although idealistically applied, use of these unproven therapies or technologies may burden patients, families, staff, and health care systems with little gain. An earnest attempt to consider the balance of benefit and burden of unproven therapies must be undertaken before they are offered to families. Clinicians should be aware of any conflict of interest or self-benefit they may receive from use of the therapy. The lack of evidence for the therapy should be carefully disclosed to the family.[20] Finally, attempts should be made to enroll in ongoing trials of the therapy or, if this is not available, at the very least details of the case should be carefully documented and published if possible. Finally, clinicians should be aware of when an innovative therapy, device, or procedure is regulated by the FDA because additional requirements exist in these situations.

Global Health

It is increasingly common for pediatric critical care clinicians to be intertwined with global heath delivery in resource-limited settings in several ways: (1) clinicians may participate in medical missions or disaster relief efforts; (2) U.S. fellowships may train clinicians from other countries; and (3) pediatric critical care clinicians may engage in helping to develop PICUs or training programs in other countries. Certainly, much can be gained from sharing knowledge and experience and developing these relationships. As always, clinicians should be careful to not impose U.S. cultural values and norms onto other cultures and societies. Importantly, ethical principles familiar to the US critical care clinician are not necessarily universal and should not be applied indiscriminately to other cultures. US clinicians may be emotionally challenged by practicing under different ethical norms (particularly

when caring for critically ill children) and should be prepared to refrain from judging unfamiliar values. Systems developed to provide critical care in other countries should meet the needs of the people who use them and should be developed to be self-sustaining[29,30] (see Chapter 21). Finally, ethical dilemmas may arise for patients and families from other countries who require critical care in the United States. It is important to engage in learning about the family's values and cultural norms when addressing ethical issues in this setting. Incorporating these sometimes unfamiliar values and norms into an ethical analysis may be challenging, particularly when they do not coincide with Western notions of patient autonomy, patient-centered best interests, or the appropriateness of disclosure of medical information to the patient.

Medical Errors

With rare exception, medical errors of all types should be disclosed to patients and families.[31,32] Truthfulness with patients and surrogates can be considered part of the fiduciary duty of a clinician. Any determination that an error should not be disclosed to a patient or family should be reviewed by a third party or a larger committee. If a clinician witnesses another's error, the clinician is similarly obligated to take steps to ensure the error is disclosed.

Relationship Boundaries

Clinicians in the PICU form relationships with patients and families at a stressful time in their lives. At times, intense, deep, caring relationships may develop; these can be meaningful and therapeutic for the clinician, as well as the patient or family. The long-standing medical culture of training clinicians to maintain emotional distance from patients and families may not only be unrealistic in the emotionally charged PICU but also contribute to career dissatisfaction and burnout. Additionally, families consistently report desiring clinicians who genuinely care about them and their child. Deep, genuine, caring relationships between clinicians and patients and families may be beneficial.[33] Care should be taken, however, to avoid nonbeneficial or harmful relationships. Romantic or overly intimate relationships should be avoided. Caution should be exercised when considering a relationship that extends beyond the walls of the PICU and boundaries of the medical relationship, including social media contact.[34]

Preventive Ethics

Many ethical dilemmas have recurring themes and common triggers and may be predicted before the conflict reaches a state of crisis. A proactive, as opposed to a reactive, approach may address, deescalate, or even prevent crisis ethics situations from arising. This would clearly be of benefit to the patient, family, staff, and institution alike. One approach is to embed an ethicist in the PICU to make rounds and identify ethical issues to be addressed proactively. Another approach is to create PICU systems to address common triggers, such as assigning continuity physicians to chronic patients. However it is accomplished, it is in everyone's interest to avoid intractable crisis ethical dilemmas.[35]

Goals for the Ethical Practice of the Intensivist

It is essential for critical care clinicians to understand the basis for complex ethical decisions and actions so that intensivists' patient care remains morally and ethically sound in the setting of high stakes, high pressures, competing needs, great uncertainty, and diverse perspectives and values. There are few absolutes in bioethics. By its nature it is a continually shifting field, to which intensivists must constantly adjust and to which intensivists must actively contribute. Despite changes and advances in this field, critical care clinicians can continually provide the best, most ethical care by understanding the history of ethical standards and current debate. Intensivists must continue to focus on compassionate and empathetic care, which will nearly always identify the right course of action. The critical care team must value collaboration and constantly work to improve their communication and mediation skills. Critical care clinicians should open their hearts to deep relationships and be willing to explore the values of others and their own. Finally, intensivists should always be open to incorporating the expertise of others who can add to their practice. An intentional focus on these qualities will promote ethically sound care even in a rapidly changing and inherently uncertain environment (Box 14.2).

Box 14.2

Goals for Ethical Practice of the Intensivist

Focus on compassionate and empathetic care

- Value collaboration with patients, families, and colleagues
- Hone relational techniques and communication and mediation skills
- Continually explore self-values and values of others
- Develop a basic approach to ethical dilemmas
- Understand the history and meaning of prevailing ethical norms applicable in the ICU
- Stay up to date on current ethical controversies applicable in the ICU
- Know when to involve experts in ethics, conflict resolution, and family and staff support

CHAPTER 15

Ethical Issues in Death and Dying

Meredith G. van der Velden, Jeffrey P. Burns

PEARLS

- Although decision making at the end of life most commonly rests with a child's parents, there may be times when a parent requests therapies that are deemed inappropriate by the clinical team. These therapies need not and should not be delivered.
- As truly futile treatment is difficult and rare to define, deliberation over these possible inappropriate therapies should focus on intensive communication and negotiation with hospital processes available for support and deliberation when this fails.
- Rationing decisions should be considered but not ad hoc for an individual patient when evaluating the appropriateness of a treatment at the end of life.
- The majority of deaths that occur in the pediatric intensive care unit do so following a decision to withdraw or withhold life-sustaining treatments.
- There is no legal or moral distinction between withdrawing and withholding treatment.
- The doctrine of double effect supports the use of aggressive treatment for comfort at the end of life including analgesia and sedation.

Many of the ethical issues that emerge in the care of the critically ill child do so at the end of life. Although many controversies still exist and new ethical dilemmas continually surface when facing death in the pediatric intensive care unit (PICU), significant progress toward a degree of consensus has been made over the years. This chapter provides an overview of ethical concerns that arise at the end of life in the PICU, including decision making near the end of life, the ethics of withdrawal and withholding of life-sustaining treatments, issues around death determination, and issues that arise after death has been declared. Much of the discussion of the delivery of end-of-life care can be found in the chapter on palliative care (see also Chapter 16).

Decision Making at the End of Life

As addressed in Chapter 14, there is little debate that decision-making authority for infants and children, particularly those in the PICU who are unable or too young to make decisions, rests with the parents.[1] In light of the diversity of individual and family values and the complexity of the decisions being made, parents are justifiably provided wide discretion in these health care decisions for their children.[2] There is, however, similar consensus that physicians have an obligation to protect their patients in a way that may involve challenging the wishes of the parents on behalf of a child's "best interests" when this rare situation arises.[3]

More than 30 years ago, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical Research[3] produced the original guiding documents for most of these issues. In addition to addressing the determination of "best interests" when approaching treatment options, the commission also discussed an approach to decision making with parents. It concluded that although decision-making authority should rest with the parents under most circumstances, there may be times when it is appropriate for the physician to act against the parents' wishes, specifically when parents choose to forgo clearly beneficial treatment and when parents prefer to provide futile treatment (Table 15.1).

TABLE 15.1

Decision Making in the Pediatric Intensive Care Unit

Physician's Assessment of Treatment Options	Parents Prefer to Accept Treatment	Parents Prefer to Forgo Treatment
Clearly beneficial	Provide treatment	Provide treatment (during review process)
Ambiguous/Uncertain	Provide treatment	Forgo treatment
Futile	Provide treatment	Forgo treatment

Although most physicians agree, and ethics and the law support, the opinion that delivering treatment that is "futile" is inappropriate, the concept of futility has been so controversial that it is rarely an effective support for a physician in overriding a parent's wishes. Regardless, most major societies including the American Academy of Pediatrics (AAP), Society of Critical Care Medicine (SCCM), and American Medical Association (AMA) do support the physician in withholding futile treatments from patients when it can be so determined.[1,4,5] The problem still rests in determining when care is "futile."

While much progress has arguably been made in our approach to cases of "futility," as practitioners in the intensive care unit (ICU), situations continue to arise in which parents wish to administer treatments and support that are deemed inappropriate and nonbeneficial by the providers. In these scenarios, how do practitioners balance the interests of the patient, family, society, and themselves? Is determining "futility" in these situations possible or even appropriate?

Burns and Truog address the concept of futility and these questions by describing historical and generational accounts of the notion of futility and, in doing so, suggest a practical approach to resolving questions of medical futility.[6] The first generation describes attempts at defining futility in order to resolve disputes with family members. These have included attempts to quantitatively (eg, treatment has been useless in the past 100 cases), qualitatively (eg, "treatment that merely preserves

permanent unconsciousness"),[7] and physiologically (eg, treatment unable to achieve its physiologic goal) define the concept. All of these definitional approaches have been largely unsuccessful in actually resolving questions of disputed therapies between families and care providers as a result of flaws inherent in the definitions, along with failure to reach consensus on the definition in the background of a pluralistic society.[8]

Following recognition that attempts to define futility failed, generation two describes the subsequent period, which attempted to address disputed cases through the use of procedures aimed at resolution. These have taken the form of individual hospital policies outlining processes to be followed in cases where the appropriateness of a therapy was brought into question and attempts at consensus between the family and clinicians failed. In general, these policies aim to represent all parties involved and most often include an ethics consultation with possible courses of action if resolution of the dispute is not achieved by mere involvement of this third party. The possible actions include further attempts at resolution, transfer of care, or judicial involvement for the purpose of, or hospital endorsement of, unilateral action on behalf of the clinical team. Ultimately, the policies transfer the decision-making authority from the bedside clinicians and family to this third party. With these processes, the major concern that arises focuses on the neutrality of the committee on behalf of the disputed parties.[9] A survey on attitudes and practices of pediatric critical care providers showed that despite most hospitals having these policies, providers do not make unilateral decisions to forgo treatment against the wishes of the family but rather provide the requested support until consensus is reached.[10] While this reports practice rather than preference, another survey demonstrated that the majority of pediatric intensivists questioned are not in support of limiting therapies against the wishes of families,[11] giving further support to the notion that even with policies in place, acting against the wishes of the family is not likely.

The final generation focuses on enhancement of early communication and negotiation with families when anticipating and making decisions about the use of life-sustaining treatments. In concert, this involves clinicians supporting each other while they respect the wishes of the family and deliver care with which they may disagree. This final generation, while not the easiest or most straightforward, may represent the approach that is most aligned with the underpinnings of dedicated critical care—to provide support for patients *and* their families through illness and death.

A final issue relevant to the discussion of decision making around the use of life-sustaining therapies in a critically ill patient is the rationing medical care. While it can be tempting to consider cost control in these discussions, as it is a pressing consideration in health care today, it should be separated from the decision of the appropriateness of a medical treatment for an individual patient. The questions of cost and appropriateness, although both important, are fundamentally different, and the approaches to answering them should reflect this. Furthermore, ICU care is known to be costly, but the limitation of its use at the end of life is not certain to result in significant cost savings.[12] Rationing at the bedside can be complicated,[13] and for this reason, the AAP has supported the separation of rationing decisions and bedside decision making for any individual patient.[14]

A multisociety statement from 2015 including the American Thoracic Society,

American Association of Critical Care Nurses, American College of Chest Physicians, European Society of Intensive Care Medicine, and Society of Critical Care Medicine provides consensus recommendations for responding to requests for potentially inappropriate treatments in ICUs. Their recommendations are grounded in shared decision-making authority between the patients and families and their clinicians. They include the following: (1) implementation of strategies to prevent intractable conflicts; (2) recommendation for use of the term *potentially inappropriate* over *futile* to describe treatments that may accomplish an effect (i.e., are not futile) but are not justifiable to provide on the basis of other considerations; (3) delineation of a process of conflict resolution in cases that remain intractable despite communication and negotiation; (4) restriction of the term *futile* to those rare cases when the treatment can be physiologically so determined; and (5) pursuit of efforts led by the medical profession at the level of policy and legislation to determine when life-prolonging treatments should not be used.[15]

Withholding and Withdrawing of Life-Sustaining Treatments

While disagreements about the use of life-sustaining treatment do arise on occasion, it is far more common that a family and the medical team reach consensus about a decision to withdraw life-sustaining therapies. Furthermore, a majority of deaths in the PICU occur after the withdrawal of life-sustaining therapies.[16,17] While there may be regional, national, and international variability in the number and percentage of patients who have a decision made to withdraw life-sustaining therapies,[17] the ethics of the process of withdrawing life-sustaining treatments remain the same.

At this stage, the difference between withdrawing and withholding treatment may come into question. Although the actions of withdrawing and withholding a therapy may feel undeniably different to families and the care team, there is no true moral or legal distinction between the two.[3] Any treatment not directed at comfort may be withdrawn or withheld if agreed upon by the family and clinical team, including, but not limited to, mechanical circulatory or ventilatory support, medications supporting the circulation, renal replacement therapy, antibiotic therapy, and hydration and nutrition. Although clinicians and families may make morally and legally defensible decisions to limit such treatments, it is never acceptable to limit care directed at providing comfort and emotional support for the patient and his or her family.[18]

Once the decision is made to focus on comfort rather than life-sustaining therapies, whether these are being withdrawn or withheld going forward, the aggressiveness of and attention to care cannot dissipate. The doctrine of double effect remains the guiding principle when considering therapies to be used at the end of life when the focus has transitioned from sustenance of life to comfort. While a contentious topic related in part to concerns of oversimplification and misplaced focus on physician intent, it remains relevant and supportive when drawing the line between possibly unacceptable (eg, euthanasia) and acceptable (eg, aggressive palliative therapy) treatment courses.[18]

As alluded to, the doctrine relies on a distinction between what is intended and what is merely foreseen by the clinician. It states that for any action that has two

effects, one good and one bad, it is justifiable if the following four conditions are met (Box 15.1): (1) the action itself must be morally good or neutral; (2) the good and not the bad effect must be intended; (3) the good effect must be a result of the action and not by means of the bad effect; and (4) the good effect must proportionally outweigh the bad effect.[19]

Box 15.1

Four Conditions of the Doctrine of Double Effect

The action itself must be good or at least morally neutral

The good effect and not the bad effect must be intended

The good effect must be a result of the action itself and not by means of the bad effect

The good effect must proportionally outweigh the bad effect

As clinicians address a number of therapies considered when treating pain and suffering at the end of life, this doctrine supports many, such as the use of analgesia and sedation. It falls short in justifying actions such as the administration of neuromuscular blockade to a dying patient, as well as other courses of treatment that might fall under the distinction of active euthanasia.

Both the American College of Critical Care Medicine of the Society of Critical Care Medicine and the American Thoracic Society provide guidelines on the delivery of care at the end of life with specific recommendations on management of symptoms.[18,20] Among other topics, the guidelines provide a framework for consideration of withdrawing, withholding, or administering therapies. In general, whether deciding to continue or stop a therapy (eg, antibiotics, mechanical ventilation) or considering the initiation of a new therapy for symptom management (eg, analgesia), the decisions should center around the patient's needs and should incorporate ongoing patient assessment and consideration of established guidelines.[18]

Analgesia

Along with the avoidance of painful interventions, it is well accepted that pharmacologic interventions aimed at pain relief are indicated when withdrawing life-sustaining treatments. The goal for a patient who has had life-sustaining treatments withheld or withdrawn is to treat any signs of discomfort or pain. Consistent with the doctrine of double effect, the focus of analgesic medications, including opioids with their known side effect of respiratory depression, should be directed at this perceived pain and not to directly cause death. This is best accomplished by careful patient assessment and use of objective scales when appropriate and available, as well as attention to the appropriate dosing titrated to effect, based on a patient's prior exposure to the medications being considered. The medication dosing will vary patient to patient, and any guidelines or procedures should reflect this anticipated variability. To reiterate, the goal of administering

these therapies is only to treat patient discomfort and not to hasten the dying process or treat concerns of family members with medication for the patient. The latter concern can and should be dealt with in other ways. In addition to emotional and psychologic support for family members, anticipatory guidance on the process can help avoid the situation when a family may perceive discomfort and request medications without objective signs from the patient.[18]

Sedation

Most sedative agents lack analgesic properties, but their role in symptom management at the end of life is no less relevant. In addition to treating symptoms such as anxiety and agitation, they may also have a role in the treatment of refractory pain and suffering not relieved by analgesic medications. This latter indication works by lowering patient consciousness until symptoms are relieved. Sedation used in this manner has been labeled terms such as *palliative sedation, total sedation,* and *terminal sedation,* the last of which has received much criticism.[21] While critics of the practice claim a slide toward active euthanasia, the dominant view is that when intended and titrated to relieve symptoms, not to achieve unconsciousness or death, this does not represent euthanasia and is a key component in the delivery of quality end-of-life care.[22] As with titration of analgesics, the doctrine of double effect remains the principle that puts intent as central and defends the process. In a survey of US physicians, there exists broad support for the acceptance of unconsciousness as a side effect of sedation to treat suffering and refractory pain.[23] In its statement on palliative care in children, the AAP endorses the use of adequate analgesia and sedation to treat pain and other symptoms in patients with terminal conditions, while explicitly not supporting the practice of physician-assisted suicide or euthanasia.[24]

Neuromuscular Blockade

Neuromuscular blocking agents have no analgesic or sedative properties. Furthermore, while the pharmacologic activity of these agents may give the *appearance* to others (ie, family members) that a patient is without distress, in doing so they actually mask many of the objective signs of suffering we use when titrating medications for such symptoms. There is, thus, no role for the initiation of neuromuscular blockade at the end of life.[18,25] The more challenging question arises when determining what to do with existing neuromuscular blocking agents when the team and family have come to the decision to withdraw mechanical ventilation. With the principal goal being to adequately treat a patient's discomfort at the end of life when life-sustaining treatments have been withdrawn, attempts should be made to restore neuromuscular function, including delay in withdrawal when reasonable, in order to regain access to many of the signs and symptoms used to titrate medications for pain and discomfort. There may be times, however, when the restoration of function cannot be accomplished in a reasonable time period due to factors such as altered drug metabolism and clearance resulting from organ dysfunction and length of treatment with such agents. In such cases, the benefit of delaying withdrawal of mechanical ventilation may be outweighed by the burden on the family that comes with this delay. In these rare cases, withdrawing mechanical

ventilation without restoration of neuromuscular function is justifiable but must be balanced with extra attention to ensuring patient comfort in the absence of typical signs and symptoms of pain or anxiety.[25] This is reflected in the SCCM recommendations for end-of-life care in the ICU.[18]

Artificial Hydration and Nutrition

As mentioned earlier, any treatment that is not directed at comfort may be withdrawn or withheld at the end of life if the family so chooses and the care team is in agreement. This no less true for the administration of artificial hydration and nutrition. Although withholding or withdrawing these therapies may be more psychologically distressing for caregivers and family, it is important to be clear that ethics and the law do not distinguish between these and other life-sustaining treatments. Guidelines of the AAP and SCCM[18,26,27] provide support for such decisions based on the same considerations of benefit and burden as with the withdrawal and withholding of other life-sustaining therapies.[1] In recognition of the unique distress that withdrawing or withholding this therapy may present, the AAP strongly recommends the involvement of ethics committees when these decisions are considered.[27]

Death Determination

The death of a patient in the ICU can occur in one of three ways: (1) following the withholding or withdrawal of life-sustaining treatments, (2) following unsuccessful resuscitation, and (3) brain death. The former two paths lead to the more widely accepted cardiorespiratory death, while the latter is a concept that has engendered controversy despite its steady legal standing.[28] According to the language of the Uniform Determination of Death Act drafted by the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research in 1981, death itself can be determined by either the "irreversible cessation of circulatory and/or respiratory functions" or "the irreversible cessation of all function of the entire brain, including the brain stem."[29] Despite the criticism of the determination of death by neurologic criteria, which centers mainly around questions of its biological validity,[28] it remains a widely recognized determination both legally and clinically and has been well accepted in pediatrics.[30,31] Furthermore, its existence allows for the possibility of organ donation in these patients in accordance with "the dead-donor rule," which states that vital organs can only be taken from someone who is dead.[32] These paradigms around organ donation are being questioned now more than ever, however, as a response to the burgeoning controversy with the notion of brain death as true biological death and with the limitation in opportunities for organ donation this requirement affords.[28,32] The details of organ donation itself are addressed in the chapter on organ donation (see also Chapter 17).

CHAPTER 16

Palliative Care in the Pediatric Intensive Care Unit

Alisa Van Cleave, Eileen Rhee, Wynne Morrison

PEARLS

- Pediatric intensivists must have a high level of competency in core palliative care skills, including communication, shared decision making, appropriate limitation of interventions, pain and symptom management, and end-of-life care.
- Medical and technologic advancements have led to a growing number of children living with complex, chronic, life-limiting illnesses. These children should receive high-quality palliative care alongside curative and life-extending therapies.
- Mastery of communication skills is a vital part of critical care training. When in doubt, talk less and listen more.
- When considering the limitations of interventions, clinicians should focus on eliciting a family's values, goals, and hopes for their child and develop recommendations for care aimed toward achieving those goals, rather than presenting a "menu" of interventions from which the family chooses.
- *Do not attempt resuscitation* (DNAR) is more appropriate terminology than *do not resuscitate* (DNR) because it does not assume that resuscitation will be successful.
- Compassionate extubation is an important ICU skill that requires meticulous planning and preparation for both family members and staff.
- When the goals of care shift toward comfort, pain and symptom management must be prioritized, using both pharmacologic and nonpharmacologic interventions.
- Care of the family extends beyond the child's death and includes bereavement services and follow-up visits with ICU staff if the family desires.
- Indications for consultation by a specialty palliative care team include complex decision making and communication support, symptom management, and transition to hospice.

Introduction

Caring for children with life-limiting illnesses is an important role for the pediatric intensivist. Over the past 2 decades, the overall mortality rate of pediatric intensive care units (PICUs) in US teaching hospitals has decreased by half, due in part to medical and technologic advancements.[1] These advancements have increased the longevity of children with diagnoses that were previously uniformly fatal and have resulted in a growing number of children who live with chronic, life-limiting conditions, many of whom are technology dependent. Children with complex, chronic illnesses represent an increasing proportion of hospitalized pediatric patients, many of whom require frequent care in the PICU.[2] In this population of patients, the intensivist must consider the child's illness trajectory, quality of life, symptom burden, and family preferences for care during each admission. Due to the broad spectrum of illnesses with variable trajectories and prognoses that characterize pediatric patients, flexible models of the balance between curative and palliative care must be employed, as depicted in Fig. 16.1.[3]

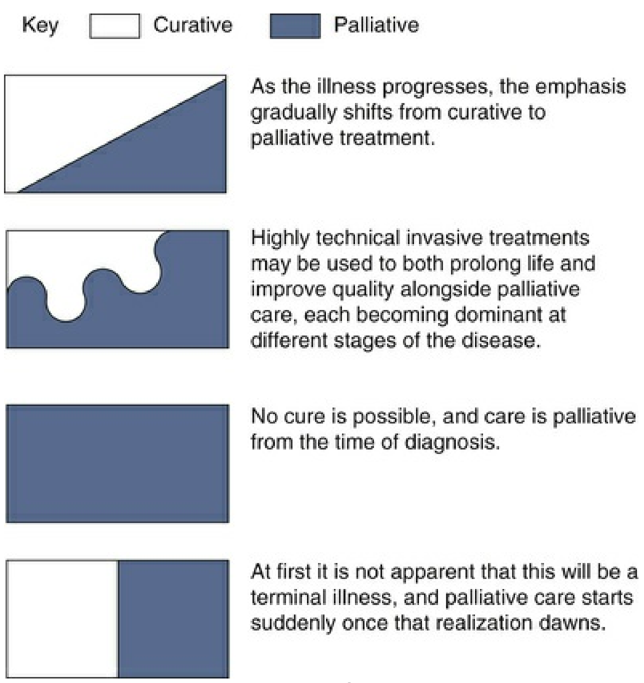

FIG. 16.1 A graphical representation of the balance between curative and palliative therapies in various clinical contexts. (From Sourkes B, Frankel L, Brown M, et al. Food, toys, and love: pediatric palliative care. Curr Probl Pediatr Adolesc Health Care. 2005;35:350-386.)

In order to adequately care for children with chronic, life-limiting conditions, as well as those who are near the end of life, pediatric intensivists must have a high degree of competency in core palliative care skills, including communication, shared decision making, appropriate limitation of interventions, and pain and symptom management. This chapter explores the practice of palliative care in the PICU by intensivists, palliative care providers, and the interdisciplinary team.

Palliative Care Consults in the PICU

The compelling need for family-centered care and the broad range of pathophysiologies that exist in ICUs demand a mixed model of integrative and consultative palliative care, which allows for a wider distribution of a limited subspecialty resource.[4,5] *Primary* palliative care is an integrative model that focuses on maximizing and standardizing palliative care practices that clinicians routinely incorporate into the care of their patients.[6,7] *Secondary* palliative care uses consultation of a palliative care team for complex, subspecialty-level problems. Secondary palliative care helps ensure that there is adequate assessment and management of symptoms, as well as attention to emotional and psychologic distress, practical and financial concerns, and spiritual and cultural needs, as part of comprehensive patient- and family-centered care.[4] (For more on patient and family-centered care, see Chapter 13.)

Indications for specialty palliative care consultation include complex decision making and communication support (for either the medical team or family), symptom management, optimization of quality of life, hospice transition, and end-of-life care that extends beyond usual care practices. Parents of critically ill children often face difficult, value-laden decisions amid bewildering amounts of information and an "irreducible amount of uncertainty."[8] Communication expertise around eliciting patient and family preferences and translating those preferences into decision making are part of the core set of skills for intensivists. Palliative care specialists can provide additional support and guidance in particularly complex situations to help elucidate goals of care for patients and families.[9]

Epidemiology of Pediatric Death in the PICU

Deaths occur in several different ways for children in the PICU. Most deaths in the United States follow a decision to limit or discontinue life-sustaining interventions, rather than failed resuscitative efforts.[1,10-15] In a recent US multi-institutional prospective study, 70% of PICU deaths occurred after withholding or withdrawing life-sustaining treatments, 16% occurred after brain death, and 14% occurred after an unsuccessful resuscitation attempt.[1]

Although there are limited data characterizing the timing of death for PICU patients, the same study revealed two distinct profiles of death in the PICU: one in which death occurred within 7 days of admission to the PICU and another in which death occurred following a longer length of hospitalization. The children in the first group were more likely to have been previously healthy and died following failed resuscitation events, whereas those who died later in their hospitalization tended to have preexisting diagnoses and DNAR orders and died in the context of withdrawal of life-sustaining technology.[1]

In many cases, particularly for children whose death occurs later in a hospitalization, there is uncertainty around the exact timing of death following the removal of life-sustaining therapies or a decision to limit escalation of life-prolonging therapies. Preparing the team and family for this uncertainty will allow an opportunity for dialogue to ensure that symptom management is appropriately addressed and that comfort is prioritized. To that end, a question may arise regarding whether the patient should remain in the PICU, be transferred to the

primary inpatient ward service, or possibly be discharged home. Many factors are involved in this question, including the complexity of symptom management, need for technologic support, a strong relationship between the patient and a specific care team, as well as provider and family comfort level with the provision of care in various locations.

Hospice Support in the Home

For a number of families, allowing their child to die at home is a great source of comfort. Hospice agencies are invaluable partners specifically skilled to coordinate and facilitate such a care plan. Hospices provide comfort-oriented medical care and psychosocial support to patients with life-limiting illnesses and their families. US hospices are independent agencies structured to be compliant with Medicare guidelines.[16,17] Hospice agencies typically provide care to adults, and few are dedicated specifically to the care of children. However, many adult hospices will care for children if a pediatric medical team advises their care. Notably, hospices do not provide shift-based home nursing care for patients. Hospice nurses visit patients on a regular basis (from biweekly to monthly, depending on their needs) to help caregivers assess symptoms and manage changes in clinical status. They are also on call 24 hours a day for support by phone and, in special circumstances, can provide continuous in-home care for up to 72 hours for patients who are actively dying. Although hospital-based palliative care teams and community-based hospices are distinct, pediatric palliative care teams work closely with hospices to help ensure a seamless transition from hospital to home.[18,19]

Communication

The importance of communication in the intensive care setting has become abundantly clear over the past 2 decades (see also Chapter 4). Health care providers communicate with families in many ways in the ICU, but the hallmark of ICU communication is the family meeting. In a typical family meeting, members of the medical team sit down with the patient's family away from the bedside to formally discuss the patient's care. Commonly, these meetings are organized by the medical team to facilitate difficult conversations, including the delivery of bad news, discussions regarding goals of care, and end-of-life care preferences.

Suboptimal Communication in the ICU

Excellent bidirectional communication between providers and families is an essential part of providing comprehensive, family-centered care in the intensive care unit.[20-22] In fact, some families deem the quality of a physician's communication skills more important than their clinical skills.[23] Failure to provide adequate communication puts patients and families at risk for poor outcomes, including anxiety, depression, and posttraumatic stress disorder.[24]

Despite its importance, studies continue to reveal that communication between families and providers in the ICU is suboptimal.[25-29] In a recent study,[30] researchers interviewed parents of children who died in the PICU regarding the communication that occurred around their child's end-of-life care. More than 70% of parents gave

constructive feedback to physicians regarding the way information was conveyed during their child's terminal illness. The most common issue raised in this study was physician availability and attentiveness to the families' informational needs. Other concerns included honesty, withholding of information, use of complex language, pacing of information delivery, providing false hope, body language, and affect during bad news delivery.

Families with Limited English Proficiency

Families with limited English proficiency (LEP) are at even greater risk of receiving poor communication from health care providers, despite using trained medical interpreters. Patients with LEP are less satisfied with physician communication than English-speaking patients, including the degree to which physicians listen, answer questions, explain concepts, and provide support.[31-35] A recent study compared the quality of communication during interpreted and noninterpreted PICU family meetings.[36] Interpreted meetings had fewer elements of shared decision making and a greater imbalance between physician and family speech. In fact, LEP families spoke for less than 4 minutes during meetings that lasted 43 minutes on average. Though this finding may be cultural to some degree, it is difficult to argue that effective, bidirectional communication can occur with so little family participation, especially when discussing such complex issues as the care of a critically ill child.

The Family Meeting as an ICU "Procedure"

Complex, value-laden decisions, such as the decision to withhold or withdraw life-sustaining therapies, are typically made during ICU family meetings. For that reason, conducting a family meeting with clear, compassionate, bidirectional communication is a critical ICU "procedure" that must be effectively taught to all trainees.[37] Importantly, because ICU family meetings are frequently organized when the medical team wants to discuss limiting or withdrawing life-sustaining measures, it is possible to foster a hidden agenda that implies that, when family meetings are conducted well, families choose to limit or withdraw interventions. In actuality, a successful family meeting is one in which the medical team elicits the patient's and family's goals and values, and a care plan is crafted that achieves their goals and honors their values.

Communication Pearls

Palliative care specialists receive extensive training on conducting difficult conversations, and they can be called on as a resource for both the medical team and family. However, effective communication of difficult and complex information is a core competency for all intensivists, and these skills must be learned early in training and honed throughout one's career. A number of strategies exist to assist clinicians in conducting these conversations,[38] one of which is the SPIKES protocol,[39] summarized in Table 16.1.

TABLE 16.1

SPIKES: A Protocol for Delivering Bad News

Set up: Find a private space with adequate seating. Never conduct a conversation of this nature without sitting down. Patient perspective: Begin by allowing the patient or family to share their understanding, concerns, and goals for the meeting. Always listen before you talk. Invitation: Obtain the family's permission to give them the information you want to share. This can also be an opportunity for a "warning shot," or a phrase that prepares the family for difficult news. As an example, one could say, "Unfortunately, I have some difficult information to share with you. Is it all right if I talk about that during this meeting?" Knowledge: Deliver the information clearly and compassionately. Go slowly, and allow for silence. Families may only hear the first piece of bad news delivered before their emotional response prevents further comprehension. Resist the temptation to continue delivering information if the family is having an emotional response. Instead, acknowledge and validate their emotions. Emotions: Though some providers may feel uncomfortable addressing emotions, families consistently report the importance of empathy from health care providers. The presence or absence of empathy can leave indelible marks on family members for years to come. If unsure how to respond, listening with empathic statements is always appropriate. Summary: Provide a brief summary of the meeting, ensuring that you have addressed the goals and concerns laid out by the family at the start of the meeting. State the next steps, and plan for future conversations.

Adapted from Baile WF, Buckman R, Lenzi R, et al. SPIKES—A six-step protocol for delivering bad news. Oncologist. 2000;5:302-311.

Phrases to Avoid

Several antiquated phrases remain in the vernacular of health care providers and must be eliminated, such as "withdrawal of care," "Nothing more can be done," and "There is no hope." Care is *never* withdrawn from a patient in the ICU. There is always more that can be done to help ensure comfort, provide support, maintain dignity, and create meaning. Allowing families to maintain hope is important.[40] Providers may worry that preserving hope and truth-telling are mutually exclusive. However, research suggests the opposite: truthful disclosure of prognostic information, even in the setting of poor prognosis, is associated with increased parental hope.[41] This may be because hope is not solely defined by a particular medical outcome. Truthful prognostic information, when delivered compassionately, can allow parents to focus on achievable hopes, such as comfort, quality of life, and meaningful relationships. Eliminating these phrases will help ensure that families do not feel abandoned by the medical team.

Though protocols and guidelines can be helpful, all providers will encounter situations in which it is difficult to know what to say or how to proceed. When this occurs, we are reminded by Elaine Meyer of the importance of "being present, not perfect."[42] Connecting with patients and families on a human level by bearing witness to their suffering will facilitate continued collaboration amid even the most difficult circumstances.

Limitation of Interventions

One of the most difficult options for a family and the medical team to consider when a child may be dying is whether advanced technologic supports offer any benefit. Such supports can include invasive or noninvasive mechanical ventilation, medical or mechanical support of the circulation, surgical interventions, renal replacement therapy, intravenous medications, or medically administered nutrition and hydration. Forgoing such interventions requires that the family and medical team agree that such therapies offer little chance of benefit, that the pain or suffering they cause is not worth the hoped-for benefit, that the therapies no longer provide a reasonable quality of life, or that they otherwise do not help to achieve important goals for the child and family. (For more on medical ethics and decision making,

please see Chapter 14.)

Do Not Attempt Resuscitation Orders

An important tool when determining desired goals is the do not attempt resuscitation (DNAR) order. Such orders historically became necessary when medical care advanced to such a degree that many "intensive care" interventions, such as mechanical ventilation or cardiopulmonary resuscitation (CPR), became the default pathway to appropriately prolong life in most circumstances.[43,44] Such orders are unique in medical care, since having the order in place is necessary to avoid performing an intervention, rather than to request it.

DNAR is becoming a more commonly used term than *do not resuscitate* as DNAR does not presuppose that resuscitation attempts will be successful. Some centers have shifted terminology for DNAR orders even further by calling them *allow natural death* (AND) orders.[45,46] The general public may have an inflated perception of the success of CPR, based somewhat on media depictions.[47] A physician's willingness to share his or her medical opinion regarding the likelihood of success of CPR, especially if that likelihood is low, may be helpful in a family's decision making. Using phrases that focus on what will be provided (eg, comfort) rather than on what will be withheld (eg, resuscitation) may help families understand the reasoning behind such choices. How choices are presented, or "framed," may affect patient and family decisions.[48-50]

In discussions with the patient and family, it is imperative that the clinician elicit the family's overall goals rather than presenting a list of all possible interventions and asking for a yes/no answer to each. Once the family has articulated their goals (eg, "going home," "avoiding painful procedures," or "waiting to see if he can get back to baseline"), then the clinician can focus on determining which specific interventions might help achieve those goals. DNAR orders are not "all or none," and a range of interventions could make sense depending on the clinical circumstances. Clarity in the orders is important, however, for team communication and consistency, especially if multiple transitions in care providers may occur.

During these discussions, it is important to avoid phrases such as "Do you want us to do everything for him?" Such phrases are nonspecific and imply that "doing" is the right course of action,[51] because the converse is to "do nothing." In circumstances where a clinician feels strongly that invasive technologic support will not lead to long-term benefit, it is acceptable to recommend against CPR or intubation as a way to protect the child from interventions that won't help.[52] Making a recommendation is an important part of shared decision making, and recommendations should be based on the goals and values articulated by the patient and family.[53] Although the ethical justification for withholding a therapy is exactly the same for withdrawing a therapy, it may be psychologically more difficult for some families to stop interventions that are already in place than it is to forgo pursuing new ones. Limitations of interventions may often therefore begin as "nonescalation" plans, with consideration of withdrawal of an intervention only if the trajectory becomes clear.

Compassionate Extubation

Discontinuing mechanical ventilation (now called *compassionate extubation*) is an important skill for all intensivists. It requires meticulous planning and symptom management. Preparing the family is an important first step. This includes determining whom should be present, asking if they would like to hold their child during extubation, and distinguishing between expected signs that are part of the dying process (eg, color change, noisy breathing) versus signs that would be treated with additional medication. A quiet, private location is preferable in which the medical team is immediately available. Care providers should avoid overly precise predictions of how quickly a patient will die following compassionate extubation, as some patients may breathe better on their own than anticipated. Providing a range of time, such as “minutes to hours” or “days to weeks,” gives families a general idea of expected time course. Preparing medications ahead of time to treat anticipated symptoms is important, and having a titration plan in place may help staff assess and respond to distress.[54] It is sometimes helpful to decrease ventilatory support shortly before extubation to assess whether the patient develops dyspnea. If the patient appears uncomfortable on lower ventilatory settings, additional doses of medication can be given before extubation. Although medication for dyspnea and agitation is essential, neuromuscular blockade should not be administered if a ventilator is being withdrawn. Neuromuscular blockade may hasten death and also makes it difficult to assess distress or determine whether additional medications for comfort are needed.[55,56] It is certainly possible to discontinue other interventions, such as vasoactive infusions, extracorporeal circulatory support, or supplementary oxygen, while awaiting resolution of neuromuscular blockade before extubation.

Pain and Symptom Management

When the goals of care shift to comfort, it is important to pay close attention to medication management and symptom control. Common symptoms at the end of life include pain, dyspnea, anxiety, and agitation. Many medications that treat these symptoms are part of routine ICU care (Table 16.2). Medication choices may differ significantly depending on how long a child is expected to live following removal of ICU interventions, what sources of pain exist, or how neurologically intact the patient is, although there is likely large variability between different centers.[57] Table 16.2 includes typical starting doses, but doses will need to be a significantly higher level if a patient has developed tolerance. Medications should be titrated to effect, with the maximum dose dictated only by side effects. For opioids and benzodiazepines, bolus doses and infusion rates may be repeatedly increased by 20% to 50% until symptoms are controlled, which typically occurs before respiratory depression. In patients without intravenous access, other routes of medication administration (transdermal, sublingual, rectal, subcutaneous) can be considered rather than increasing discomfort by necessitating needle sticks and procedures to maintain venous access.

TABLE 16.2

Medications Commonly Used for Pain and Distress at the End of Life[a]

Medication	Routes	Starting Dose	Notes
Opioids			

Morphine	PO, SL, PR, SQ, IV	0.05-0.1 mg/kg every 3-4 h Infusion: 0.01-0.03 mg/kg/h	Renally excreted; causes histamine release
Hydromorphone	PO, IV, SQ, SL	0.015 mg/kg every 3-4 h Infusion: 0.003 mg/kg/h	
Fentanyl	IV, SQ, buccal, nasal, patch	0.5-1 mcg/kg every 30 min Infusion: 1 mcg/kg/h	Transdermal patches available in 12.5, 25, 50, 75 and 100 mcg/h
Methadone	PO, IV	0.05-0.1 mg/kg every 6-12 h initially, then decrease frequency	Long acting and may accumulate; may be adjunctive for neuropathic pain via NMDA effects; prolongs QT interval; multiple drug interactions
Benzodiazepines			
Midazolam	PO, IV, SC	0.05-0.1 mg/kg every 2-4 h Infusion: 0.03-0.1 mg/kg/h	Onset of action within minutes when given IV
Lorazepam	PO, IV, IM	0.025-0.1 mg/kg every 4-8 h	Less hypotension than midazolam, slightly slower onset
Diazepam	PO, PR	0.05-0.2 mg/kg every 6-12 h	IM and IV formulations available but rarely used due to pain/phlebitis; IV form may also be given PO or PR
Other Sedatives and Adjuncts			
Ketamine	PO, IM, IV	0.2-0.5 mg/kg/dose	May be adjunctive for neuropathic pain via NMDA effects
Gabapentin	PO	10 mg/kg/day	For neuropathic pain; increase daily until 30 mg/kg/day, then reassess
Amitriptyline	PO	5 mg	For neuropathic pain; target dose 0.5-1 mg/kg/day

[a]All doses are starting doses for patients not previously exposed and may need to be escalated to much higher levels.

IV, intravenous; kg, kilogram; mcg, microgram; mg, milligram; NMDA, *N*-methyl-D-aspartate; PO, oral; PR, per rectum; SL, sublingual; SQ, subcutaneous; n/a, not applicable.

Medication Management

Opioids

Several commonly used opioids are listed in Table 16.2. Opioids treat both pain and dyspnea and may also have sedating effects. They work via central nervous system μ-receptors. Potential side effects include constipation, nausea, pruritus, urinary retention, and respiratory depression.[58,59] Side effects should be anticipated and prevented if possible (eg, with a bowel regimen). Intractable side effects can sometimes be managed by rotating to another agent in the class.[60] Some side effects, such as nausea and vomiting, may resolve over time.

Distinguishing features of specific opioids are important to mention. Codeine should be avoided because approximately 10% of the general population lacks the hepatic enzyme necessary to convert it to morphine, and up to 35% of children demonstrate inadequate conversion to morphine.[61] Meperidine should also be avoided because its metabolite, normeperidine, can accumulate and cause seizures. Fentanyl is commonly used in ICUs because of its rapid onset and titratability, but it can be problematic at the end of life if used for longer than brief periods because tolerance can develop rapidly. However, the transdermal (patch) form is often useful for patients who are unable to tolerate enteral medications and no longer have IV access. Morphine leads to histamine release, which can cause pruritus, and hypotension, which may improve with rotation to hydromorphone. At very high doses, morphine has neuroexcitatory effects that cause hyperalgesia, delirium, and myoclonus. Morphine should also be avoided in renal failure, as accumulation of its metabolites causes myoclonus.

Methadone

Methadone differs from other opioids and therefore bears special mention. It is a μ-receptor agonist, as well as an *N*-mNethyl-D-aspartate (NMDA) receptor antagonist. It has a long and highly variable half-life. Its NMDA effects can sometimes improve pain control in patients who have become tolerant to high doses of other opioids, and it may also be effective in treating neuropathic pain. Its long half-life can lead to drug accumulation, which may cause late-onset side effects such as obtundation. Careful adjustment of dosing schedules is required. Methadone has many drug-drug interactions that require careful review. It can also prolong the QT interval, so it is prudent to screen patients with an electrocardiogram before its initiation.

Other Pharmacologic Agents

Acetaminophen or NSAIDs (eg, ibuprofen, naproxen, ketorolac) may be useful adjuncts to the medications listed in Table 16.2. However, doses of these medications cannot be escalated because of the risk of toxicity. Combination agents, such as acetaminophen with oxycodone, should be avoided because acetaminophen limits the ability to escalate the opioid component.

Ketamine is a dissociative anesthetic that also has NMDA effects. It offers excellent pain control and may have opioid-sparing benefits. However, it can cause disturbing hallucinations. Similar to methadone, it may have advantages for neuropathic pain.

Other useful techniques to achieve pain control include regional nerve blocks, lidocaine patches, and occasionally treatment with steroids.

Symptom Management

Pain

A multitude of agents are available for the treatment of pain, many of which are discussed earlier (see also Chapters 134 and 135). Neuropathic pain may be treated by methadone, gabapentin, or amitriptyline. Steroids and IV bisphosphonates are useful adjuncts for pain relief due to malignant bone pain. Nonpharmacologic adjuncts to pain control may also be useful. Research suggests that integrative therapies, such as art and music therapy, can be effective adjuncts for pain treatment in children with cancer.[62]

Dyspnea

Opioids are the mainstay of treatment for dyspnea. Nebulized opioids are sometimes used, although they have not shown consistent benefit in controlled trials.[63,64] In addition to opioids, dyspnea may be improved with a fan blowing in the face. Other respiratory support such as supplementary oxygen or noninvasive positive pressure can be considered if they enhance comfort, but there is no mandate to use them if they add to distress or prohibit patient disposition to another location (eg, home or outside of the ICU) that would be preferable to the family. If noninvasive ventilation is used, excessive positive pressure should be avoided as it is more likely to lead to discomfort and skin breakdown.

Agitation and Anxiety

Benzodiazepines are often useful to treat agitation or anxiety at the end of life and may also help decrease opioid requirement.[65] Low doses may be sufficient, but some

patients may require escalation to sedating doses. A calm, quiet environment can be helpful, but so can distracting or enjoyable activities.

Nausea and Vomiting

Several agents are available for the treatment of nausea and vomiting. Ondansetron or metoclopromide are often effective. Benzodiazepines are also useful. Phenothiazines, such as promethazine and prochlorperazine, are efficacious but can be very sedating. They may also cause extrapyramidal side effects, which diphenhydramine can help mitigate. Olazapine or haloperidol can be used when other agents are ineffective.[66]

Seizures

Seizures can also occur at the end of life, for which benzodiazepines are a good first-line agent. Levetiracetam or valproate is sometimes used to prophylax against seizures in patients at high risk (eg, with brain tumors).[65]

Bowel Obstruction

Bowel obstruction is a particularly difficult situation to manage. Decompression with nasogastric drainage may improve symptoms. Relieving constipation is often important. Steroids may be beneficial if the obstruction is due to a mass. Motility agents can be helpful, but they may also increase pain. Octreotide (intravenous or subcutaneous) has been used to decrease intestinal secretions and may improve symptoms such as vomiting.[67] Palliative surgery can be considered, but the degree and duration of benefits versus burdens should be carefully weighed.[66]

Palliative Sedation

Rarely, symptoms may remain uncontrolled at the end of life despite maximal medical management. In such circumstances, palliative sedation may be considered. *Palliative sedation* is “the use of sedative medications to relieve intolerable suffering from refractory symptoms by a reduction in patient consciousness.”[68,69] Benzodiazepines, barbiturates, dexmedetomidine, or propofol can be used. Additionally, propofol has advantageous effects against nausea, pruritus, seizures, and myoclonus, while dexmedetomidine is useful because it does not cause respiratory depression. Sedation to unconsciousness can be justified when symptoms cannot be managed by other means and death is considered “imminent” (eg, within hours to days). Protocols have been published that guide the implementation of palliative sedation, which include prerequisite consensus by an interdisciplinary team that symptoms are truly refractory and that the patient is imminently dying of a terminal illness.[70]

Practical Aspects of Care at the End of Life

As the death of a patient is anticipated, several practical aspects of care must be accomplished in a timely and sensitive manner (see also Chapter 15). Specific issues to address with family and staff before the patient's death include notification of an organ procurement organization (OPO), discussion of expected signs or symptoms

the child may exhibit, cultural or spiritual needs during or after the dying process, sibling support, and autopsy. Hospitals are required to notify the local OPO when the death of any patient is anticipated so that the OPO may determine whether the patient could be a potential organ or tissue donor. Generally, the OPO must be contacted before the patient's death to determine candidacy. If the patient is a suitable donor, the clinical team then notifies the family that a representative from the OPO will meet with them to answer questions about organ donation and determine whether the family wants to participate. A timely discussion about organ donation is particularly crucial when donation after circulatory death (DCD) is considered. (For more on organ donation, please refer to Chapter 17.)

The exact timing and trajectory of symptoms are often difficult to predict at the end of life. Therefore conversations should generally focus on how to identify discomfort and the medications and techniques (eg, oxygen, positioning, massage) that will be provided to relieve suffering. Frequent communication between the medical team and family optimizes care for the dying child, and it may help alleviate anxiety for both staff and family. Further, addressing a family's specific cultural or spiritual needs around death is an important way to provide additional support. Using child life specialists to help siblings comprehend the death of their brother or sister is an invaluable source of support for the family during the end-of-life process.

Addressing the family's wishes regarding autopsy before the child's death will allow time for thoughtful consideration and appropriate planning. The physician who discusses obtaining an autopsy ideally should know the patient and family well, and the physician must know the indications for and limitations of autopsy in order to advise the family. Some families choose autopsy to obtain more information on the etiology of death, if it is unclear, or potentially to provide reassurance that the underlying disease was irreversible. On occasion, an autopsy may disclose an unrecognized genetic disorder that may have clinical implications for the family.[71] An autopsy could also answer questions that may arise in the future. Some families are motivated to pursue autopsy because the findings could contribute to medical knowledge and possibly help another child and family. If a family elects to pursue an autopsy, a designated physician must offer a follow-up visit to review the results.

After the declaration of death, families may desire privacy with their child. During this time, essential documentation can be performed. The death summary note includes a brief description of the patient's medical history and the events that led to death. The rationale used to titrate sedation and analgesia, if administered, is important to document. The death certificate, which is separate from the death summary note, must be completed promptly. The coroner or medical examiner must be notified to determine whether a forensic autopsy is indicated, which typically occurs in cases of trauma or abuse but varies with jurisdiction, and families should be informed if such a decision is made. Notification of other providers from different care teams, including subspecialty teams, referring providers, and primary care providers, is important. If the child attended school or day care, or had home nursing or hospice support, the agencies should be notified, with the parents' permission.

Care of Family and Staff After a Child's Death

The death of a child is a tragic event that affects all who are touched by it. Grief

support is a crucial part of the ongoing care that bereaved families need after their child dies, and these services are typically provided by referral to a community or hospital-based bereavement program. Such programs provide ongoing support and frequent assessments to identify complicated grief when it occurs. Bereaved families of chronically ill children often describe a sense of "double loss," both for their child and for their medical team, who cared for them over the course of months or years.[72] Family members may also grieve the same child in very different ways and on different timelines, which may cause distress for some providers, but is actually a normal phenomenon. In addition, sibling grief is sometimes overlooked due to the varying ways that children in different developmental stages express emotion. Parents often try to protect siblings from the trauma of the ill child's end-of-life care, though studies show that this strategy leaves siblings feeling excluded and abandoned, which persists long into bereavement.[73]

Staff members in the ICU are also impacted by the death of a child and are at risk for compassion fatigue and burnout due to repeated exposure to secondary trauma.[74] The American College of Critical Care Medicine Task Force guidelines for support of the patient and family in the ICU setting recommend structured support mechanisms for staff, such as debriefing sessions,[75] which can be facilitated by social work, spiritual care, or palliative care. For some individuals, these sessions provide a safe forum to discuss their feelings about a particular patient or experience, which can help process grief. Others may benefit from developing personalized ways to process stress or grief, which can include any number of activities, such as exercise, reflective writing, outdoor activities, engaging in a spiritual practice, or meeting with a counselor or therapist regularly. In addition, some staff members choose to send condolence letters or attend memorial services for children as a way to further support the family, honor the memory of the child, and process their own grief. Research suggests that these gestures are positively received by families[76] and can be beneficial for some providers. Finally, recent studies suggest that follow-up meetings between bereaved parents and critical care physicians are beneficial to both parties and are crucial to providing family-centered care.[77]

CHAPTER 17

Process of Organ Donation and Pediatric Donor Management

Thomas A. Nakagawa

PEARLS

- Involvement of pediatric critical care specialists has improved the quality and number of organs recovered. Additionally, more organs from pediatric donors are being transplanted into children.
- Donor management is crucial to the successful recovery of organs for transplantation. Management of the potential pediatric organ donor requires knowledge of the physiologic derangements associated with this specific patient population.
- Timely involvement of the organ procurement organization coordinator allows medical professionals to dialogue and improve authorization rates while assisting families with end-of-life care issues.
- Determination of neurologic death in children is based on clinical criteria that are consistent across the age spectrum.
- Donation after the circulatory determination of death (DCD) allows donation to occur from patients with a catastrophic brain injury who do not progress to neurologic death. Success with organs transplanted from DCD donors continues to occur in many centers.
- The sustained practice of pediatric DCD donation continues to account for more than 10% of the total number of DCD donors nationally.
- Neonatal donation provides another valuable source of organs for transplantation.

Introduction

The demand for transplantable organs continues to increase at a rapid pace, far exceeding the number of organs available for transplantation. Approximately 1.5%

of the patients on the national transplant wait list are children 18 years of age or younger.[1] Similar to adults, the majority of children waiting for a transplant have end-stage renal failure and are in need of a kidney, followed by children with hepatic disease who are waiting for a liver.[1] In contrast to the increasing number of adults on the wait list, the number of children added to the national transplantation wait list has remained relatively stable. Importantly, the number of children receiving organ transplants has increased, and pediatric donors are providing more organs for pediatric patients awaiting transplantation.[1,2] Additionally, wait listed patients in need of a transplant who in the past died from their organ failure are now living longer lives due to improved pharmacologic and medical management. In fact, some of these patients improve and may not require transplantation at all, further reducing the number of children on the national wait list. Nonetheless, children continue to die waiting for a lifesaving transplant, with the highest death rate observed in children younger than 1 year of age.[1,2] Although the number of children who die while on the wait list for a needed organ has decreased, the number of children who are removed from the wait list and die because they become too sick to transplant has increased.[1] The need for more organs and improved therapies to preserve organ function for those waiting for a transplant is clear in this population of patients. The American Academy of Pediatrics recognizes this need and supports organ donation emphasizing education, the need to shape public policy, and a system in which organ procurement, distribution, and cost are fair and equitable for children and adults.[3]

Each state has laws or regulations for the determination of death, which have in most cases been modeled after the Uniform Determination of Death Act (UDDA).[4] The UDDA states that an individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions or (2) irreversible cessation of all functions of the entire brain (including the brain stem) is dead (see also Chapter 15). A determination of death must be made in accordance with accepted medical standards. Organ donation can occur following neurologic death (donation after brain death [DBD]), circulatory death (donation after circulatory death [DCD]), or through living donation. Donor organs recovered for transplantation include heart, lungs, liver, kidneys, pancreas, and intestines. However, the type of donation affects the organs recovered. Most organ donation occurs following death established by neurologic criteria. In both children and adults, the number of donors following neurologic death has decreased since the early 2000s.[1,5] This decline in pediatric donors has occurred for many reasons, including improved medical and surgical treatments, vaccinations that have reduced deaths associated with childhood infectious diseases, safety restraints, education and awareness regarding health hazards affecting children, and pediatric critical care specialists who have reduced morbidity and mortality for critically ill or injured children.

Missed opportunities for organ donation occur in many medical institutions.[6-8] Frequently these lost opportunities occur when families decline the option of donation. The hospital experience, difficulty understanding death, and racial barriers may contribute to the lack of authorization for donation.[9] Donor families are more likely to understand neurologic death and have a positive hospital experience compared with families that chose to not authorize donation.[10] In some cases families are not even given the opportunity for donation because the medical team may not recognize an eligible donor. Organs available for transplantation may be lost because

of caregivers' lack of familiarity with appropriate donor management, or opportunities for donation may be denied by medical examiners or coroners who fear losing evidence and the ability to successfully prosecute cases in situations where accidental or nonaccidental trauma has claimed the life of a child.

Unique issues exist with the process of organ donation and transplantation in children. Parents and guardians must act as surrogate decision makers without benefit of being guided by the donor's wishes, as is often possible with adults. Size and weight constraints can the limit acquisition and use of organs recovered from children. Technical challenges related to surgical procedures in smaller children and infants and age-related variation in the timing associated with the declaration of brain death can result in organ deterioration and affect the viability of organs for transplantation. Specialized care required for the management of critically ill children and pediatric organ donors may be lacking at institutions that have limited expertise and support for children. This includes expertise from nursing and critical care specialists, as well as support from pediatric neurologists, neurosurgeons, general surgeons, other pediatric specialists, and pediatric support staff, who understand the unique needs of children and their families.

The process of donation involves identification of a potential donor, determination of neurologic death in a timely manner, authorization for organ donation, management of the donor, and recovery of organs for transplantation. The process of donation begins when a critically ill or injured child is identified as a potential donor with a timely referral to the organ procurement organization (OPO). Early involvement and collaboration with the OPO allows coordination of the donation process and enhances the chances of successful authorization and recovery of viable organs for transplantation.[3,7,11] Medical management of the potential pediatric organ donor requires knowledge of the physiologic derangements associated with this patient population. Hemodynamic instability, alterations in oxygenation and ventilation, metabolic and endocrine abnormalities, and coagulation disturbances are common. Support and care of the family provided by a team of physicians, nurses, social workers, chaplains, family service providers and organ donation specialists, and other support staff trained in the unique aspects of pediatric medicine are integral to the care of these children and their families.[7] Each of these elements is essential to ensure the successful recovery of organs from this select group of patients.

Role of the Pediatric Intensivist and Critical Care Team in the Process of Organ Donation

Effective donor management is crucial to the successful recovery of organs for transplantation. The integral involvement of the pediatric intensivist and the critical care team in the management of critically ill and injured children has been a foundation of the clinical practice in many successful pediatric centers. Caring for critically ill children and their families through all phases of illness including end-of-life issues should be a seamless transition. The continuum of care for the dying patient who progresses to death and becomes a donor requires the expertise of the pediatric intensivist and critical care team to not only manage and prevent deterioration of organ systems and loss of transplantable organs but to help the

family deal with the death of their child. Preserving the option of organ donation allows families to make the decision about donation for their child.[7,8] Involvement of critical care specialists, especially in pediatrics where there is a limited and decreasing number of donors improves the quality and number of organs recovered.

It is federally mandated that the OPO be informed of any impending death. The OPO should be notified in a timely manner prior to the death of the patient. Suitability of the potential donor needs to be determined and issues regarding donation need to be discussed with the medical team and the OPO prior to approaching the family. Utilizing OPO coordinators and appropriately trained requestors to obtain authorization by families has been a successful practice in the adult arena; however, pediatric critical care practitioners have learned that children and their families are different. Collaboration between the OPO and the pediatric intensivist is essential to determine the best way to approach families about authorization for donation.[7,8,11,12] Parents seem to prefer discussions regarding donation with the pediatric intensivist or a member of the health care team they have come to trust, rather than the OPO coordinator.[7,13] Additionally, one study noted that timing of the first request relative to discussions of brain death did not influence the decision to donate organs, but authorization for donation was more likely when parents had sufficient time to discuss this issue.[13] These concepts are vastly different from the traditional approach of the OPO coordinator requesting donation and decoupling the death and authorization process. Improved communication between the health care team and the OPO is imperative. Many institutions have adopted a team approach when discussing donation with families. This best practice is encouraged by the United States Department of Health and Human Services Organ Donation Collaborative, which has led to increased donation rates.[14] Best practices promote coordinated efforts between OPO coordinators and medical professionals to improve authorization rates while assisting families with end-of-life care issues. Involvement of palliative care teams has also been identified as another resource to assist the ICU team and parents and families facing end-of-life issues with their child.[15-18] In addition to the benefits of organ donation to the transplant recipient, there are psychologic and social benefits for the potential donor and the family.[3,8,19,20]

Determination of Neurologic Death

The majority of donations occur following neurologic death.[1] The dead donor rule states that patients must be declared dead before removal of vital organs in order for transplantation to occur.[21] Therefore accurate determination of neurologic death is essential before efforts at organ recovery proceed. Determination of neurologic death must occur in a timely and efficient manner for several reasons: It allows the family to begin the grieving process as they prepare for the loss of a loved one; it allows the process of organ preservation and preparation for recovery to begin; and if donation is not planned, medical therapies can be stopped, allowing redistribution of scarce ICU resources to other critically ill and injured patients.

Good donor management is imperative for the recovery of viable organs for transplantation. Hemodynamic instability and organ dysfunction account for a loss of up to 25% of potential donors when donor management is not optimized.[22] Furthermore, institution of hormonal replacement therapy (HRT) early in the

donation process may assist with stabilization of the donor, improve the quality of organs recovered, and enhance posttransplant graft function.[23-27]

Determination of neurologic death in children is a clinical process based on specific criteria, which are consistent across the age spectrum. No unique legal issues differentiating the declaration of neurologic death exist for children. However, determination of irreversible injury and neurologic death can be more difficult in younger patients, resulting in age-based recommendations and two separate neurologic examinations.[28,29] Criteria for the determination of neurologic death in infants and children were revised in 2011.[28,29] The updated guidelines provide criteria to determine neurologic death for infants greater than 37 weeks' estimated gestational age to 18 years of age.[28,29] The clinical history, cause of coma, and neurologic injury must be determined to ensure that an irreversible condition has occurred. Physical examination criteria rely on the coexistence of coma and apnea in a child who is neither hypothermic nor hypotensive for age and whose examination is not affected by sedatives or neuromuscular blocking agents. The neurologic criteria to determine death in infants and children are listed in Table 17.1. Absence of neurologic function is defined by the following features on physical exam: midposition or fully dilated nonreactive pupils, absence of spontaneous eye movements induced by oculocephalic (when feasible) or oculovestibular testing, absence of bulbar function, cough, corneal, gag, and rooting reflexes, and absent respiratory effort when challenged with elevated carbon dioxide levels that would otherwise induce respiratory effort in such a patient. Two neurologic examinations and apnea tests separated by an observation period are required to establish the diagnosis of neurologic death in the United States.[28,29] The duration of observation between examinations is based on age. Ancillary studies are not mandatory to make a determination of neurologic death. The need for ancillary studies will be determined by the physician caring for the child based on history and the ability to complete the clinical examination and apnea testing.[28,29] If clinical examination and apnea testing cannot be safely completed, an ancillary study should be used to assist with the determination of death. The examination results must remain consistent with neurologic death throughout the observation and testing period.

TABLE 17.1

Neurologic Examination Criteria for Brain Death Determination in Infants and Children[28,29]

1. Coma. Patient must lack all evidence of responsiveness. Noxious stimuli should not produce a motor response other than spinally mediated reflexes.
2. Apnea. The patient must have the complete absence of documented respiratory effort (if feasible) by formal apnea testing demonstrating a $PaCO_2$ ≥60 mm Hg *and* >20 mm Hg increase above baseline $PaCO_2$.
3. Loss of all brain stem reflexes including the following: • Midposition or fully dilated pupils that do not respond to light • Absence of movement of bulbar musculature including facial and oropharyngeal muscles • Absent gag, cough, sucking, and rooting reflexes • Absent corneal reflexes • Absent oculovestibular reflexes
4. Flaccid tone and absence of spontaneous or induced movements, excluding spinal cord events such as reflex withdrawal or spinal myoclonus.
5. Reversible conditions or conditions that can interfere with the neurologic examination must be excluded prior to brain death testing.

Determination of neurologic death for any infant or child requires establishing and maintaining normal physiologic parameters. Before the neurologic examination or

neurodiagnostic testing can be meaningful, correction of hypotension and hypothermia must occur. Targeted temperature management and hypothermia protocols are being used more frequently as a treatment following cardiac arrest and traumatic brain injury. Hypothermia can affect drug metabolism and the clinical examination to determine neurologic death of a critically ill patient. Adequate time following rewarming is crucial prior to initiating testing for neurologic death. Current North American adult and pediatric guidelines emphasize a minimum core body temperature of >35°C (95°F).[28-31] The current pediatric guidelines for neurologic death suggest waiting at least 24 hours following rewarming before instituting testing for neurologic death. A period greater than 24 hours may be required to ensure that diagnostic error following targeted temperature management does not occur.[32-34] Additionally, conditions that can interfere with the neurologic examination or factors capable of imitating brain death must be excluded. Conditions such as severe hepatic or renal dysfunction, inborn errors of metabolism, metabolic disturbances, or toxic ingestions may play a role in the clinical presentation of the comatose infant or child. These conditions should be considered and, if identified, appropriate treatment instituted to correct the derangements resulting in coma. There may be instances where these conditions cannot be corrected and additional ancillary testing may be required to confirm neurologic death. Testing for drug intoxications including barbiturates, opiates, and alcohol should be performed as indicated. The half-life of sedative agents must be considered when determining the appropriate timing of the clinical examination. Longer-acting or continuous infusion of sedative agents and recent administration of neuromuscular blocking agents can interfere with the neurologic examination. These agents should be discontinued for a reasonable amount of time to allow adequate clearance of the drug(s) prior to initiating electroencephalogram (EEG) testing and clinical examination for neurologic death. Delayed drug metabolism in hypothermic patients or patients with hepatic or renal dysfunction should also be considered prior to testing for neurologic death. Barbiturates reduce cerebral blood flow (CBF); however, there is no evidence that high-dose barbiturate therapy completely arrests CBF. A radionuclide CBF study or cerebral arteriography can be utilized in patients with high-dose barbiturate therapy to demonstrate the absence of CBF.[28,29,35,36] Clearance of neuromuscular blockers can be confirmed by use of a nerve stimulator.

The apnea test is a critical and essential component of the clinical examination to determine neurologic death. Testing for apnea must allow adequate time for the partial pressure of carbon dioxide ($PaCO_2$) to increase to levels that would normally stimulate respiration. Apnea testing must be performed safely while maintaining normal oxygenation and stable hemodynamics. Patients should be preoxygenated with 100% oxygen to prevent hypoxia and enhance the chances of successfully completing the apnea test. Mechanical ventilatory support should be adjusted to eliminate ventilation, allowing the $PaCO_2$ to rise while observing the patient for spontaneous respiratory effort. False reports of spontaneous ventilation have been described while patients were maintained on continuous positive airway pressure (CPAP) for apnea testing despite having sensitivity of the mechanical ventilator reduced to minimum levels.[28,29,37] Attaching a self-inflating bag valve system, such as a Mapleson circuit, to the endotracheal tube (ETT) or tracheal insufflation of oxygen using a catheter inserted through the ETT has also been employed to provide supplemental oxygen. High gas flow rates with tracheal insufflation may promote

CO_2 washout preventing adequate $PaCO_2$ rise during apnea testing. Additionally, adequate gas outflow must be ensured to prevent barotrauma. The $PaCO_2$ should be measured and allowed to rise to 60 mm Hg or greater and 20 mm Hg above the baseline $PaCO_2$ while the patient is continually observed for any spontaneous respiratory movements over a 5- to 10-minute period. These respiratory criteria account for infants and children with chronic respiratory disease or insufficiency who may only breathe in response to supranormal $PaCO_2$ levels. The apnea test is consistent with neurologic death if no respiratory effort is observed during the testing period. The patient is placed back on mechanical ventilator support following apnea testing until death is confirmed with a second clinical examination and second apnea test. If apnea testing cannot be completed because of hemodynamic instability, desaturation, or an inability to reach a $PaCO_2$ of 60 mm Hg and a greater than 20 mm Hg increase above the baseline $PaCO_2$, or if there is any concern regarding the validity of the apnea test, an ancillary study should be pursued to make the determination of neurologic death. If an ancillary study is utilized, a second clinical examination and apnea test must also performed. Any respiratory effort is inconsistent with neurologic death.

Recommended clinical observation periods between examinations in children differ from those of adults, with a greater duration suggested for younger children. The updated guidelines continue to emphasize that the younger the child, the more cautious one should be in determining neurologic death. Table 17.2 lists the recommended observation periods based on the age of the infant or child from the Updated Guidelines for Determination of Brain Death in Infants and Children.[28,29]

TABLE 17.2

Recommended Observation Periods to Determine Brain Death in Infants and Children[28,29]

Term infants (37 weeks estimated gestational age) to 30 days of age • Two examinations and apnea tests separated by at least 24 hours[a]
Greater than 30 days of age to 18 years of age • Two examinations and apnea tests separated by at least 12 hours[a]

[a]The observation period may be decreased if an approved ancillary study is used. A second clinical examination and apnea test must be performed following the ancillary study to declare death.

Ancillary studies can provide additional supportive information to assist in the determination of neurologic death. These studies are useful when the clinical examination or apnea testing cannot be safely completed due to the underlying medical condition of the patient, when there is uncertainty about the findings of the neurologic examination, or if a confounding medication effect may be present. Ancillary studies are not necessary if the determination of neurologic death can be made based on clinical examination criteria and apnea testing. Ancillary studies may be utilized to expedite the determination of neurologic death by reducing the clinical observation period, potentially increasing viability of transplant tissue. However, in the circumstance that an ancillary study is equivocal, the observation period can actually be increased until another study or clinical examination and apnea test can be performed to confirm neurologic death. Ancillary studies can be helpful for social and medical reasons. These studies may allow family members to better comprehend that neurologic death has occurred and may be important in situations

where death is the result of homicide. Ancillary studies are not a substitute for a complete physical examination.

Four-vessel cerebral angiography evaluating anterior and posterior cerebral circulation remains the gold standard to determine blood flow when testing for neurologic death; however, this test is difficult to perform in small children and requires technical expertise that may not be available in every facility. Furthermore, transporting a potentially unstable patient to the angiography suite carries additional risk that can complicate this process. For these reasons, cerebral angiography is rarely performed in infants and children. EEG documentation of electrocerebral silence (ECS) and absence of CBF using radionuclide CBF study remain the most widely available and useful ancillary studies to assist with the diagnosis of neurologic death in infants and children. These studies are more easily accomplished at the bedside, without the need for extraordinary technical expertise. Radionuclide CBF studies have been used extensively with good experience.[38] Use of the portable gamma camera for radionuclide angiography has made CBF studies more accessible, allowing for the study to be undertaken at the bedside.[38,39] This study is becoming a standard in many institutions replacing EEG as an ancillary study to assist with the determination of neurologic death in infants and children.[28,29,40] EEG and radionuclide CBF studies are both accepted ancillary studies used to assist the clinician in determining neurologic death in infants and children. EEG may be more specific although less sensitive than the radionuclide CBF study. EEG testing evaluates cortical and cellular function, whereas radionuclide CBF testing evaluates flow and uptake into brain tissue. Each of these tests requires the expertise of appropriately trained and qualified individuals who understand the limitations of these studies to avoid misinterpretation. Specific criteria for these studies must be met to determine neurologic death.[28,29] Transcranial Doppler sonography and brain stem audio evoked potentials have been utilized[41-43] but have not been studied extensively or validated in children.[28,29,44,45] These studies along with CT angiography, perfusion MRI, and magnetic resonance angiography-magnetic resonance imaging (MRA-MRI) cannot be relied on as dependable or validated ancillary studies at this time.[28,29,45]

Ancillary studies are least sensitive in the neonatal age group.[28,29,46] Limited experience with ancillary studies performed in the newborn younger than 30 days of age indicates that EEG is less sensitive than CBF in confirming a diagnosis of brain death. Sensitivity remains quite low, however, even with CBF for this age group.[28,29,46,47] The younger the child, the more cautious one should be in determining neurologic death. If there is any uncertainty about the examination, apnea testing, or the ancillary study, continued observation is warranted. Additional clinical evaluations and apnea testing or a repeat ancillary study followed by a second clinical examination and apnea test should be performed to make the determination of neurologic death.

Once death has been declared, appropriate documentation of the clinical examination, apnea test, and any ancillary study should be noted. The updated guidelines for the determination of neurologic death in infants and children encourage the use of the incorporated guidelines checklist to assist with standardizing the process and documentation of neurologic death in children.[28,29]

Technologic advances continue to affect our ability to determine circulatory and neurologic death. In certain circumstances, determination of neurologic death may

be complicated by mechanical support such as extracorporeal membrane oxygenation (ECMO) or the use of advanced ventilation modes.[48,49] The updated brain death guidelines state that apnea testing should be performed safely. Apnea testing should be aborted if the patient becomes hemodynamically unstable or pulse oximetry oxygen saturations fall to less than 85%.[28,29] Performing apnea testing for a patient supported with ECMO has been safely accomplished.[50,51] The patient is placed on a flow-inflating bag valve system and hypercapnia can be induced by reducing the sweep gas or adding exogenous CO_2 to the circuit, thus allowing CO_2 to rise to an appropriate level to stimulate respiration. The rate of CO_2 rise will be variable depending how much the sweep gas is reduced.[50] Adding exogenous CO_2 theoretically may reduce the duration of the apnea test; however, this technique has not been reported. Patients supported on advanced modes of ventilation may not tolerate apnea testing. Additionally, apnea testing may be impaired by sedation and use of neuromuscular blockades that are commonly used with advanced modes of ventilation. The updated guidelines for the determination of neurologic death in infants and children make no provisions for patients with cyanotic heart disease. These patients are desaturated, not desaturating, and there are no standards to determine what level of oxygen saturation should be used before apnea testing is terminated. In these situations an ancillary study such as radionuclide CBF is recommended to assist with the determination of neurologic death.

Determining neurologic death has great implications with profound consequences. The clinical diagnosis of neurologic death is highly reliable when made by experienced examiners using established criteria.[28,29,52,53] There are no reports of children recovering neurologic function who met adult brain death criteria on neurologic examination.[28,29,47] Diagnosis must never be rushed or take priority over the needs of the patient or the family. Appropriate emotional support for the family should be provided, including adequate time to grieve with their child after death has occurred. Readers are encouraged to become familiar with guidelines in their respective institution.

Brain Death Physiology

Progression to neurologic death results in neuroendocrine dysfunction requiring specific interventions to preserve organ function. Efforts to control cerebral perfusion pressure, hemodynamic manifestations of herniation, and loss of central nervous system (CNS) function all contribute to the instability that routinely occurs during and after the progression to neurologic death. These physiologic changes clearly affect end-organ viability in the prospective organ donor. Understanding the physiologic changes and anticipating associated complications with neurologic death are therefore critical for organ function and recovery.

Loss of CNS function causes diffuse vascular regulatory and cellular metabolic injury.[54] Neurologic death resulting from cerebral ischemia increases circulating cytokines,[55] reduces cortisol production,[56] and precipitates massive catecholamine release. The combination of these factors results in physiologic deterioration and ultimately end-organ failure if left untreated.

Cerebral blood flow is approximately 50 mL/100 g per minute and consumes 15% of the cardiac output.[57] Without substrate consumption by the brain, glucose needs

are reduced and the patient is prone to hyperglycemia. As neurologic death occurs, cerebral metabolism is further decreased and carbon dioxide production falls resulting in a reduction in $PaCO_2$. Hypothermia should be anticipated as a result of hypothalamic failure and loss of thermoregulation. Additionally, impaired adrenergic stimulation results in loss of vascular tone with systemic vasodilation and increased heat loss. Ischemia of the anterior and posterior pituitary occurs, leading to neuroendocrine dysfunction and pituitary hormone depletion. This results in inhibition or loss of hormonal stimulation from the hypothalamus with subsequent fluid and electrolyte disturbances and eventually cardiovascular collapse, if left untreated.

Hemodynamic deterioration that occurs with neurologic death is initiated by a massive release of catecholamines, commonly referred to as a sympathetic, catecholamine, or autonomic storm. This release of catecholamines is associated with cerebral ischemia and intracranial hypertension and manifests clinically as systemic hypertension and tachycardia.[54,58] During this autonomic storm, organs are exposed to extreme sympathetic stress from direct neural stimulation or from significant increases in endogenous catecholamines. The local effects of this sympathetic stimulation include increased vascular tone, effectively reducing blood flow and potentially causing ischemia to these organs.

This autonomic storm also has direct effects on the myocardium, as the surge of catecholamines increases systemic vascular resistance (SVR), myocardial work, and oxygen consumption.[59] Ischemic changes occur as a result of the imbalance between myocardial oxygen supply and demand resulting in subendocardial ischemia.[54,60] Myocardial ischemia impairs cardiac output leading to dysfunction of other organs. Left ventricular end-diastolic pressure rises, causing pulmonary edema. This condition may be exacerbated by displacement of systemic arterial blood into venous and pulmonary circulations due to catecholamine-mediated systemic vasoconstriction. Increased pulmonary vascular resistance and right heart volume overload may displace the ventricular septum into the left ventricle, further impairing cardiac output by impeding left ventricular filling.[61] Progression to neurologic death results in a cascade of inflammatory mediators being released, causing vasodilation as loss of sympathetic tone and catecholamine depletion occurs.[61-63] Additionally, a shift from aerobic to anaerobic metabolism occurs as a result of ischemia and the depletion of pituitary hormones affecting cardiac performance and end-organ function.

Following the determination of neurologic death and the decision to proceed with organ donation, efforts to reduce intracranial pressure are abandoned and care shifts toward providing adequate circulation and oxygen delivery to preserve vital organ function for transplantation. Subsequent care may differ from management before death. Decreased intravascular volume, caused by efforts to reduce CBF and control intracranial pressure (eg, volume restriction and diuretic agents), must be corrected. Correction of metabolic derangements such as hypernatremia from the use of hypertonic saline and hyperglycemia associated with catecholamine release and reduced cerebral metabolism is essential to optimize organ function prior to transplantation. Attention to volume loss from osmotic diuresis associated with hyperglycemia and diabetes insipidus (DI) following neurologic death must be anticipated and addressed to prevent cardiovascular collapse. Hemodynamic management goals are directed at maintaining normal peripheral perfusion and

blood pressure for age. Additional donor management goals include the normalization of carbon dioxide tension (PCO_2), normalization of temperature, and correction of any other metabolic disturbances. Any existing infections should continue to be treated until organ procurement occurs. Even if no infectious disease concerns exist, antibiotics are commonly administered prior to organ recovery. Donor management goals are listed in Table 17.3. Progression from neurologic death to somatic death and loss of transplantable organs can result if appropriate care is not instituted.[8,22,61] Aggressive donor management optimizes organ function and affects the quality of organs recovered.[8,26,61] Aggressive donor management results in more transplantable organs and improved graft function,[23-27] potentially reducing hospital stay and decreasing morbidity and mortality for the transplant recipient.

Modified from Nakagawa TA. North American Transplant Coordinators (NATCO) Updated Donor Management and Dosing Guidelines. Lenexa, KS: NATCO; 2008.

Physiologic Considerations in the Management of the Pediatric Organ Donor

Management of the donor is a continuum of care extending from admission of a critically ill child to the recovery of organs for transplantation. The critical care team must effectively treat the potential donor and correct the physiologic derangements that follow neurologic death. The goal of therapy is to restore and maintain adequate oxygenation, ventilation, and perfusion to vital organs, thus preserving their function for successful transplantation.

Treatment of Hemodynamic Instability

Cardiac instability is the greatest limiting factor to successful organ recovery. Of all the physiologic abnormalities encountered in the prospective organ donor, the cardiovascular system is fraught with the greatest complexity and variation. The tremendous physiologic derangements associated with neuroendocrine dysfunction require specific interventions to restore normal physiology.

The sympathetic storm associated with cerebral ischemia and intracranial hypertension is a predictably transient phenomenon. Although end-organ ischemia can occur from intense hypertension, treatment with antihypertensive agents may not be warranted and indeed can create additional problems with perfusion when this phase of sympathetic outflow has passed. If hypertension is severe and treatment is felt to be indicated, a single IV dose or continuous infusion of a short-acting antihypertensive agent such as hydralazine, sodium nitroprusside, esmolol, or labetalol can be administered and titrated to effect. One must anticipate the profound vasodilation and hypotension that will occur following neurologic death and be prepared to appropriately resuscitate the patient to restore normal circulation and perfusion.

Once neurologic death occurs, sympathetic outflow ceases and catecholamine depletion occurs leading to a loss of sympathetic tone and vasodilation. This results in profound and abrupt hypotension with release of proinflammatory mediators initiating a cascade of molecular and cellular events with resultant ischemia and reperfusion injury to vital tissues.[62] Management goals during this phase of patient care are directed at aggressive restoration of circulating volume, optimizing cardiac output and oxygen delivery to the tissues, and maintaining normal blood pressure for age (see Table 17.3). Aggressive restoration of circulating volume and utilization of catecholamines to support blood pressure are mainstays of treatment.[63] Intravascular volume replacement can occur with isotonic crystalloid solutions such as normal saline or colloid solutions such as 5% albumin. Packed red blood cells can be used for the anemic patient or plasma for the patient with a coagulopathy. The use of artificial plasma expanders such as Hespan or dextran for volume resuscitation should be avoided because large volumes of these agents can promote coagulation disturbances and impair renal function.[8,64-66] Commonly used inotropic agents such as dopamine, dobutamine, and epinephrine can be titrated to effect. Catecholamines and dopamine appear to have immunomodulating effects that may help blunt the inflammatory response associated with brain death and improve kidney graft function.[67,68] Vasopressors such as norepinephrine, vasopressin, and phenylephrine can be used in situations where there is profound vasodilation and low systemic vascular resistance. Although sometimes necessary, the administration of high-dose vasoactive agents can be associated with reduced perfusion to donor organs, potentially jeopardizing their viability prior to recovery and transplantation. Many OPOs routinely use a combination of inotropic support, volume resuscitation, and HRT for donor management. The use of HRT with agents such as thyroid hormone, steroids, vasopressin, and insulin is common during donor management, especially in situations where significant inotropic support is required.[23-26,62,69] In addition to the impact of hypovolemia, acidosis, hypoxia, and hypercarbia, electrolyte disturbances can alter myocardial performance affecting suitability of organs for transplantation. These disturbances must be corrected to enhance the chances of successful organ recovery. Clinical characteristics, such as blood pressure and central venous pressure (CVP), and biomarkers, such as mixed venous oxygen

saturation and serum lactate levels, serve as guides to adequate cardiac performance and tissue oxygen delivery. Echocardiography can provide useful information about filling pressures, wall motion abnormalities, and ventricular shortening or ejection fractions. Serial echocardiograms are routinely employed in donor management and performed to assess cardiac function as treatment of the donor progresses. In many instances, cardiac performance will improve with aggressive resuscitation and institution of HRT following neurologic death.[8]

Certain clinical indicators of end-organ perfusion may not be reliable once brain death has occurred. Urine output may not be a good clinical indicator of intravascular volume when DI is present. After death of the brain stem, heart rate may not be a reliable sign of intravascular volume status because there is a loss of beat-to-beat variation, lack of vagal tone, and fixed heart rate. Perfusion may also be affected as temperature instability, and hypothermia can result in delayed capillary refill time. Biomarkers such as mixed venous oxygen saturation and serum lactate levels may usefully guide cardiac management and manipulation of oxygen delivery to tissues. Elevations in serum lactate and the development of a metabolic acidosis provide evidence of tissue ischemia and should prompt immediate attention. Importantly, an elevated serum lactate may be present following CNS or multisystem trauma and may persist following neurologic death or with profound hepatic dysfunction.

Arrhythmias can occur during progression to, or following, neurologic death. The catecholamine storm triggered by adrenergic stimulation results in myocardial ischemia and can cause necrosis of the conduction system promoting rhythm disturbances. Tachydysrhythmias can be seen prior to neurologic death in response to the catecholamine storm. Bradyarrhythmias may not be responsive to atropine because of denervation of the heart following neurologic death. Epinephrine is the pharmacologic treatment of choice if bradyarrhythmias occur. Other factors that contribute to arrhythmias include hypoxemia, hypothermia, cardiac trauma, and the pro-arrhythmic properties of inotropes. Hypotension from hypovolemia and vasodilation causes poor cardiac output and metabolic acidosis. Electrolyte and metabolic disturbances, specifically hypomagnesemia, hypocalcemia, and hypokalemia that occur with DI, may also precipitate rhythm disturbances. Identification and correction of the underlying cause of the arrhythmia are essential to address and treat rhythm disturbances.

Hormonal Replacement Therapy

Significant volume resuscitation and inotropic support are commonly required to correct severe cardiovascular derangements following neurologic death. Anterior pituitary hormone deficits can result in thyroid and cortisol depletion and may contribute to the hemodynamic instability encountered in patients who have progressed to neurologic death.[56] HRT to restore aerobic metabolism and replace hormone deficiency from the hypothalamus and pituitary, augment blood volume, and reduce the use of inotropic support while optimizing cardiac output is commonly used to support this patient population. The use of HRT has allowed a management strategy where blood pressure and normovolemia are maintained using a minimum number of vasoactive agents.

Hormonal replacement therapy in adult donors is controversial with correlations

of hormone use, cardiac function, and variable clinical outcomes noted.[23-26,69,70-73] In one adult series HRT was shown to reduce the need for vasoactive infusions in 100% of unstable donors and to abolish the need in 53% of such donors.[74] Decreased inotropic requirements have also been noted in children who received levothyroxine and vasopressin as part of donor management following neurologic death.[75] Although studies are limited, HRT seems to be a reasonable consideration in situations where the hemodynamic status of the child is refractory to conventional therapy with fluid and inotropic administration. HRT has been associated with an increased number of organs recovered from donors.[22-25,76] No published studies are available in children; however, one unpublished abstract retrospectively reviewed 1903 pediatric donors.[1] HRT was associated with significantly increased odds of having the liver and at least one kidney and lung transplanted. There was no significant increase in the odds of the heart being transplanted. The greatest benefit of HRT in donor management may in fact be improved graft function following transplantation.[23,76-78] Given these observations many OPOs have adopted the use of HRT as a routine part of donor management.[8] Commonly used agents and doses for HRT in pediatric donors are listed in Table 17.4.

TABLE 17.4

Pharmacologic Agents Used for Hormonal Resuscitation in Children

Drug	Dose	Route	Comments
Desmopressin (DDAVP)	0.5 mcg/hr	IV	Terminal half-life = 75 min (range 0.4-4 hr) Titrate to control urine output (2-4 mL/kg/h) May be beneficial in patients with an ongoing coagulopathy
Vasopressin (Pitressin)	0.5 milliunits/kg/hr	IV	Half-life = 10-35 min Titrate to control urine output (2-4 mL/kg/h) Hypertension can occur
Levothyroxine (Synthroid)	0.8-1.4 mcg/kg/hr Maximum 20 mcg/hr	IV	Titrate to effect Bolus dose 1-5 mcg/kg can be administered (maximum dose 20 mcg) Smaller infants and children require a higher bolus and infusion dose
Triiodothyronine (T3)	0.05-0.2 mcg/kg/hr	IV	Titrate to effect
Methylprednisolone	20-30 mg/kg Maximum dose 2 grams	IV	Dose may be repeated in 8-12 hours Fluid retention and glucose intolerance can occur
Hydrocortisone infusion	<25 kg 1 mg/kg/hr 26-35 kg 50 mg/hr 36-45 kg 75 mg/hr >45 kg 100 mg/hr	IV	Maximum dose should not exceed 100 mg/hr
Insulin	0.05-0.1 units/kg/hr	IV	Titrate to effect to control blood glucose levels Monitor for hypoglycemia

Modified from Nakagawa TA. North American Transplant Coordinators (NATCO) Updated Donor Management and Dosing Guidelines. Lenexa, KS: NATCO; 2008.

Impaired cardiac performance following neurologic death is due to myocardial injury associated with the catecholamine storm. Additionally, reduced free triiodothyronine (T3) levels may impair mitochondrial function and deplete energy stores. Animal studies have shown that diminished circulating levels of triiodothyronine and thyroxine[54] impair oxygen utilization. The effects of thyroid hormone on myocardial contractility are complex and can be immediate or delayed. The acute inotropic properties of T3 may occur as a result of beta-adrenoreceptor sensitization or may be completely independent of beta-adrenergic receptors.[78-81] Furthermore, T3 administration may play an important role in maintaining aerobic

metabolism at the tissue level after neurologic death has occurred.[82] Beneficial hemodynamic effects in brain-dead patients receiving T3 administration have been variable.[78,79] Levothyroxine (Synthroid) and triiodothyronine (T3) are the two IV thyroid agents available for administration. Triiodothyronine is used in some centers for HRT; however, the cost of this medication may be prohibitive. Dosing of thyroid hormone for the pediatric organ donor is weight based and not well established. One retrospective study in which younger children received larger bolus and infusion doses than older children demonstrated enhanced weaning of inotropic support in children who progressed to brain death.[75]

Corticosteroids such as hydrocortisone are another pharmacologic agent routinely used by many centers for HRT to assist with hemodynamic support. There are few data demonstrating that hydrocortisone provides hemodynamic benefit in the potential pediatric organ donor.[62] However, treatment of the donor with high doses of corticosteroids to reduce inflammation associated with neurologic death and modulate immune function may improve donor organ quality and posttransplant graft function.[8] Additionally, the potential benefit of hydrocortisone and other steroids may lie in their ability to alter adrenergic receptors and regulate vascular tone by increasing sensitivity to catecholamines.[83,84] Steroids have also been shown to stabilize pulmonary function, reduce lung water accumulation, and increase lung recovery from donors.[85-89]

The combination of thyroid hormone and corticosteroids may be used to reduce vasoactive agent dose requirements in children. Additionally, vasopressin for the control of DI can reduce the need for inotropic support. HRT may provide the greatest benefit to the recipient of transplanted organs by improving donor organ quality.

Management of Pulmonary Issues for the Potential Pediatric Organ Donor

Increasing success with lung transplantation for the treatment of patients with end-stage lung and pulmonary vascular disease has placed a premium on the acquisition of lungs from the donor pool. Children waiting for a lung transplant constitute less than 5% of the national pediatric wait list.[1] However, the demand for lungs far exceeds availability because lungs are the organs most likely to be found unsuitable for transplantation. Recovery of lungs for transplantation accounts for 7% to 22% of the multiorgan donor pool.[69,90] The low percentage of lung recovery for transplantation reflects stringent donor selection criteria and a lack of suitable organs for transplantation. Every effort should be made to preserve lung function using protective lung strategies. Lung protective strategies have the potential to salvage marginal lungs for transplantation; however, in many instances these strategies are not implemented, resulting in the loss of potential lung donors.[90]

Many factors contribute to the limitations associated with the acquisition of lungs for transplantation. Neurogenic pulmonary edema may develop during the progression or upon completion of neurologic death resulting in high ventilator settings. Blunt trauma in children resulting in pulmonary contusion/hemorrhage accounts for a large portion of injuries to the thoracic cavity. Inhalational or thermal injury can damage the lungs and airway structures. Infectious etiologies can

compound the effects of existing lung disease or injury. Often these injuries are the reason the patient has become an organ donor. Furthermore, the lungs are particularly vulnerable in the face of critical illness, leaving them susceptible to complications such as fat emboli, pulmonary emboli, aspiration pneumonia, ventilator-associated pneumonia, and atelectasis.[87] Each of these disorders is associated with lung injury and impaired ventilation and oxygenation that diminish the lung suitability for transplantation.

The physiologic aberrations that accompany neurologic death can also result in end-organ damage rendering lungs unsuitable for transplantation. Management of pulmonary physiology is often complicated by the development of pulmonary edema as neurologic injury progresses.[61] The sympathetic storm associated with neurologic death causes systemic and pulmonary vasoconstriction. Neurogenic pulmonary edema occurs as pulmonary venous pressure rises, causing pulmonary capillary wall disruption and the evolution of pulmonary edema.[91] This predictable deterioration of pulmonary function increases the lung's vulnerability to injury following neurologic death.[90,92] Massive brain injury may in fact act as a preconditioning factor that renders the graft more susceptible to subsequent lung damage and increases the risk of posttransplant graft failure.[92]

Lung protective management strategies have been developed as a result of the complex physiology and vulnerability of the lungs following brain death. Measures to protect donor lungs have resulted in improved recovery and successful transplantation of these organs.[93,94] Management strategies include measures such as diligent pulmonary toilet with frequent suctioning, patient turning, clearance of mucous plugs, and airway evaluation with flexible bronchoscopy.[87,95] Ventilator management with attention to recruitment maneuvers such as sustained inflations and positive end-expiratory pressure (PEEP) have been advocated to avoid the development of atelectasis and treat pulmonary edema associated with the catecholamine storm that occurs with neurologic death.[94,95] The benefit associated with the use of inflation maneuvers and PEEP must be balanced against the risk of barotrauma and effects on preload that can potentially embarrass cardiac output in the donor with myocardial dysfunction. Volume administration and inotropic support may be required if blood pressure is affected by this maneuver. These cardiovascular effects can be minimized if adequate preload is provided prior to escalation of PEEP. Colloid solutions have been recommended to minimize the accumulation of pulmonary edema.[95] Additionally, albuterol has been shown to enhance clearance of pulmonary edema in an animal model[70] and to improve mucociliary clearance.[87] Corticosteroids are frequently utilized in the donor and have been shown to reduce lung water accumulation and stabilize pulmonary function.[85-88] Another novel therapy involves the use of naloxone to improve gas exchange in donor lungs.[96] The exact mechanism of action of naloxone to enhance pulmonary function is unknown, but free radical scavenging has been suggested.

Ventilatory requirements may become minimal in the donor as neurologic death occurs. Respiratory alkalosis is common as metabolic production of carbon dioxide from the brain ceases and compliance of the chest wall changes. Restoring normocarbia with a goal of 35 to 40 mm Hg in the child who has progressed to neurologic death is ideal given the effects of pH on unloading characteristics of oxygen from hemoglobin. Avoiding overdistention of the lungs during mechanical and manual ventilation is crucial to reduce the risk of barotrauma or further

pulmonary injury.[87,94] Donor management goals include achieving a PaO_2 of >100 mm Hg, oxygen saturation of >95% using the least amount of oxygen necessary. Adequate alveolar recruitment can be obtained using a tidal volume of 8 to 10 mL/kg and PEEP of 5 cm/H_2O or lower tidal volumes of 6 to 8 mL/kg and higher PEEP of 8 to 10 cm/H_2O. Elevation of the head of the bed and use of a cuffed endotracheal tube with high cuff pressures to reduce aspiration risk are also advocated.[87] Additionally, oral care using chlorhexidine may reduce the chances of a ventilator-associated infection. Frequent turning, pulmonary toilet, and chest physiotherapy when appropriate are essential to prevent atelectasis. Prone positioning may be beneficial to optimize ventilation perfusion matching. Serial chest radiographs are commonly obtained to identify correctable issues or evaluate pulmonary pathology. Donor Management Goals for oxygenation and ventilation are summarized in Table 17.3.

An oxygen challenge test is routinely performed to determine the suitability of the lungs for transplantation. Transplant surgeons prefer a PaO_2/FiO_2 ratio >300 on a FiO_2 of 1 and a relatively clear chest radiograph. Many OPOs advocate early flexible bronchoscopic evaluation of the lungs to address correctable issues and maximize ventilation strategies to improve lung function. Bronchoscopy can help to clear mucous plugs or blood clots that may contribute to impaired oxygenation.

Fluid and Electrolyte Disturbances

Fluid and electrolyte disturbances in the pediatric donor are the result of physiologic abnormalities following neurologic death, as well as consequences of earlier medical management. Commonly encountered derangements include dehydration, hyperglycemia, sodium, potassium, and calcium disturbances. Metabolic fluctuations associated with progression toward neurologic death require meticulous management of fluids and electrolytes. If left untreated, these abnormalities can adversely affect organ viability.

Intravascular volume depletion is frequently encountered in the child with traumatic brain injury who has progressed to neurologic death. Fluid restriction is commonly employed along with hypertonic solutions and osmotic diuretics in the management of cerebral edema. Another contributor to intravascular volume depletion is osmotic diuresis from hyperglycemia secondary to corticosteroid and catecholamine use and the increased availability of glucose from a loss of cerebral metabolism. Furthermore, DI compounds sodium and water imbalance if not aggressively treated. The potential donor must be adequately volume resuscitated, as guided by CVP, perfusion, serum electrolyte concentrations, and serial lactate measurements. Restoring intravascular volume is crucial to maintain organ viability.

Diabetes Insipidus

Diabetes insipidus occurs in many neurologically dead patients, and if left untreated it can have profound effects on the donor (see also Chapter 85). Ischemia and ultimate necrosis of the posterior pituitary lead to a loss of central antidiuretic hormone (ADH). The loss of ADH results in uncontrolled urine output with free water losses resulting in severe hypernatremia, severe dehydration and hypovolemic

shock, and eventual cardiovascular collapse. Hypernatremia (serum sodium >155 mEq/L) can affect organ suitability for transplantation and has been associated with poorer graft outcome following liver transplantation.[8,97]

In addition to hourly maintenance of intravenous fluids, one-quarter or one-half normal saline can be used to replace urine output in excess of 3 to 4 mL/kg, until pharmacologic replacement therapy is implemented. Glucose should be avoided in renal replacement fluids to prevent further exacerbation of hyperglycemia and osmotic diuresis. Enteral free water supplementation administered through a nasogastric tube can be used to correct severe hypernatremia. Rapid osmolar shifts during correction of hypernatremia are inconsequential because neurologic death has already occurred. DI frequently requires pharmacologic treatment with ADH to reduce ongoing free water loss. Pharmacologic agents such as vasopressin or desmopressin (DDAVP) are routinely utilized in HRT protocols to control excessive urine output associated with DI. These pharmacologic agents have specific indications and side effects that must be considered when contemplating their use to treat DI.[98] Donor management goals for treating DI include maintaining a normal serum sodium level and reducing excessive urine output. With refractory DI, a combination of vasopressin and desmopressin may be indicated to control urine output. Pharmacologic treatment is intended to reduce and not completely stop urine output.

Vasopressin is a polypeptide hormone secreted by the hypothalamus and stored in the posterior pituitary. Vasopressin acts on V_1 and V_2 vasopressin receptors stimulating contraction of vascular smooth muscle with resultant vasoconstriction. It has a short half-life of 10 to 20 minutes, and unlike desmopressin it has no effect on platelets.[8,99] Vasopressin can be administered by bolus or continuous IV infusion. The most desirable features of this agent derive from its ease of titration to control urine output. When discontinued, its effects are short lived. Vasopressin is administered at doses of 0.5 milliunits/kg/hr and can be titrated to control urine output to 2 to 4 mL/kg/hr.[98,99] By titrating in this way one preserves renal function and avoids volume overload and metabolic abnormalities such as hyponatremia and hyperkalemia. Vasopressin acts synergistically with catecholamines and can reduce the need for additional catecholamine support in the neurologically dead donor.[24,75] This pharmacologic agent is ideal for the donor with DI and hemodynamic instability requiring inotropic support. Vasopressin infusions commonly require rapid titration to control excessive urine output. The infusion may need to be reduced after several hours to avoid complete loss of urine output.[100] High doses of vasopressin, especially when combined with other vasopressors with alpha stimulation, may potentially reduce splanchnic perfusion including hepatic and pancreatic blood flow. Additionally, vasoconstriction and increased smooth muscle contractility may affect coronary and pulmonary blood flow.[60] Excessive dosing of vasopressin should be avoided to preserve end-organ function.

Desmopressin acetate (DDAVP) is a more potent synthetic polypeptide structurally related to vasopressin. This agent lacks smooth muscle contractile properties and is more specific for the V_2 vasopressin receptor. Desmopressin enhances platelet aggregation and has a longer half-life of 6 to 20 hours when administered as a single IV dose.[101,102] Desmopressin may be a preferred agent for the correction of hypernatremia in hemodynamically stable donors who require no inotropic or vasopressor support or the donor with ongoing bleeding issues.

Desmopressin can be administered by continuous infusion at 0.5 mcg/hr and titrated to control urine output or as a single IV dose.[98,103] Intramuscular and intranasal administration can result in erratic absorption and should be avoided. The terminal half-life of desmopressin administered by continuous IV infusion is 75 minutes with a range of 0.4 to 4 hours.[103] The longer half-life of desmopressin may be less desirable compared to the shorter half-life of vasopressin in potential kidney donors. However, desmopressin therapy may be discontinued 3 to 4 hours prior to organ recovery.[98] Fluid replacement for excessive urine output can be administered as needed for the short period of time prior to organ recovery.

Oliguria

Oliguria can be seen with volume depletion, acute renal insufficiency or failure, and overly aggressive pharmacologic management of DI. If urine output falls to less than 1 mL/kg/hr and does not improve after decreasing or discontinuing vasopressin or desmopressin, intravascular volume status must be evaluated and appropriately treated. If urine output is not improved following volume expansion, the initiation of inotropic or vasopressor support may improve urine output. Furosemide (Lasix) or mannitol can be utilized to stimulate urine output in the patient with adequate intravascular volume status. A selective dopamine agonist such as fenoldopam can be used to enhance urine output and may provide renal protection in the normotensive or hypertensive patient.[104]

Glucose, Potassium, and Calcium Derangements

Neurologic death causes major hormonal alterations resulting in insulin resistance and gluconeogenesis. Hyperglycemia as a result of corticosteroid and catecholamine use and increased availability of glucose due to the loss of cerebral metabolism can lead to an osmotic diuresis, exacerbating an already depleted volume status in the donor. Hyperglycemia can be avoided by frequently assessing blood glucose concentration and making appropriate adjustments in the dextrose concentration in IV fluids. If these simple maneuvers are unsuccessful in controlling blood glucose levels, an insulin infusion should be instituted to maintain glucose levels within a reasonable range (60–200 mg/dL). Although target glucose levels for insulin therapy in the deceased donor continue to be debated, uncontrolled hyperglycemia should be treated.[8] Serum glucose levels should be closely followed to avoid hypoglycemia.

Potassium derangements can result from diuresis, renal insufficiency, steroid administration, and acid-base disturbances. Potassium can be supplemented if hypokalemia is significant. The adverse effects of hyperkalemia are clearly more hazardous than those of hypokalemia. The adverse effects of hypokalemia most likely to affect the potential donor are dysrhythmias.

Hypocalcemia occurs commonly secondary to large volume replacement with colloids such as albumin, massive blood transfusions that result in large amounts of citrate reducing free calcium concentrations, and sepsis. Ionized calcium levels should guide the use of calcium supplementation.

Coagulation Abnormalities and Thermoregulatory Instability

Coagulation abnormalities can arise secondary to the release of tissue thromboplastin and cerebral gangliosides from injured brain.[60] Additionally, the catecholamine surge associated with traumatic brain injury may contribute to coagulation disturbances.[105] Synthetic plasma expanders such as hespan or dextran can promote coagulation disturbances and are not recommended for volume replacement.[8,64,66] Thrombocytopenia and platelet dysfunction can be induced by common drugs such as heparin, antibiotics, beta-blockers, calcium channel blockers, histamine H_2 receptor antagonists, tromethamine, and hespan.[106] Patients with liver disease have reduced synthesis of vitamin K–dependent clotting factors. A dilutional coagulopathy can occur from massive transfusions if coagulation factors are not replenished. Coagulation abnormalities can also be exacerbated by hypothermia. Coagulopathy can be corrected using fresh frozen plasma, platelets, cryoprecipitate, and restoring and maintaining normothermia. The goal of blood product replacement for coagulopathy should be tailored accordingly based on the abnormalities encountered. Coagulation abnormalities should be addressed prior to transport of the donor to the operating suite for organ recovery. A minimum platelet count of 75,000/uL should be obtained prior to recovery of organs in the operating suite. The use of aminocaproic acid (Amicar), an antifibrinolytic agent, and other similar hemostatic agents are not recommended for treatment of bleeding because microvascular thrombosis may be induced in donor organs.[60]

Hypothermia commonly occurs following neurologic death due to loss of hypothalamic-pituitary function controlling temperature response. Vasodilation with an inability to compensate for heat loss by shivering or vasoconstriction is a common cause of thermoregulatory instability in this patient population. Additionally, infusion of large volumes of room temperature IV fluids to treat DI and volume depletion contributes to hypothermia. Hypothermia can promote cardiac dysfunction, arrhythmias, coagulopathy, a cold-induced diuresis secondary to decreased renal tubular concentration gradient, and a leftward shift of the oxyhemoglobin dissociation curve resulting in decreased oxygen delivery to the tissues.[107] Radiant warmers, warm blankets, thermal mattresses, warm IV fluids or a blood warmer for infusion of blood products, and environmental warming will help maintain body temperature. Additionally, heating-inspired gases can assist in controlling body temperature. Prevention of hypothermia is essential to prevent deterioration of the potential organ donor.

Medical Examiner/Coroner Issues and Organ Donation for Children

Many children who die from head injuries are victims of trauma. When a child's death is ruled a homicide, great sensitivity is required to preserve the integrity of the criminal investigation. Successful recovery of organs from these patients, and prosecution of the perpetrator, can still occur in most cases with close cooperation between forensic investigators, treating physicians, the transplant team, and the

OPO.[3,8,108-114] In fact, there is no reported case law where organ donation has resulted in loss of evidence and inability to prosecute a perpetrator involved with the death of a child. Early involvement of the medical examiner or coroner and protocols to facilitate organ recovery in homicide cases can decrease denials for organ donation.[110-113] Involvement of the district attorney during protocol development should also be a consideration. Efforts to reduce the number of medical examiner denials for donation continue to occur at a national level and are supported by the National Association of Medical Examiners.[114] Despite these national efforts many transplantable organs from potential pediatric donors continue to be lost because of medical examiner/coroner denials.[6]

Donation After Circulatory Death

Although the majority of recovered organs are from donors following neurologic death, donation after circulatory death (DCD) provides another source of valuable organs for transplantation. Formerly known as the non–heart-beating organ donor or donation after cardiac death, DCD is not a new way to recover organs for transplantation. Prior to guidelines to determine neurologic death, cadaveric organs were routinely recovered after death was declared following loss of circulation.

DCD allows recovery of organs from patients with catastrophic brain injury who do not progress to neurologic death. The discussions and decision to donate organs can only occur after the decision to withdraw life-sustaining medical therapies has been made. This avoids the perceived ethical conflict that the patient is being allowed to die primarily to recover organs. Routine end-of-life care, including comfort measures, is provided for these patients just as would be the case for any patient where withdrawal of medical therapies occurs. Specific criteria must be met for organs to be recovered by this method. Circulatory arrest must usually occur within 60 minutes of withdrawing medical therapies. The time constraint is important because longer periods to achieve circulatory arrest will result in organ ischemia rendering potential transplant tissue useless. Following loss of pulse pressure (mechanical asystole), the patient is observed for 2 to 5 minutes before recovery of organs can occur. This 2- to 5-minute observation period is crucial to ensure that auto resuscitation of the heart with restoration of circulation does not occur. If mechanical asystole is consistent with circulatory death following the observation period, organs are recovered for transplantation. Importantly, loss of circulatory function and not electrical activity (electrical asystole) is required to determine death. Determination of when a patient will develop loss of circulation can be difficult to predict. Scoring tools have been developed in an effort to determine if death will occur within the specified time period for donation to occur.[115-117] These tools should be used in conjunction with the physical examination, discussion with the critical care team and OPO to determine donor suitability, and likelihood of progressing to death in the allotted time period. If circulatory cessation does not occur within 60 minutes, the patient is returned to the ICU, procurement of organs is aborted, and continued comfort measures are provided for the patient. Families must be prepared for the possibility that death may not occur within the specified time period. If this situation occurs, continued comfort measures for the patient and ongoing family support should continue. DCD donation requires close collaboration among the critical care team, the operating room staff, and the OPO to

ensure the successful recovery of organs.

The reevaluation of this method of donation was prompted by the increasing need to meet the demands of a growing national transplant wait list.[118,119] There have been significant increases in the number of DCD donors since the early 2000s.[2] This sustained practice of organ recovery in children accounts for more than 10% of all DCD donors during this time period.[1] DCD has the potential to increase organ donation in children.[2,120-124] Individual numbers of DCD donors may be small at any one pediatric center, but the collective impact from all pediatric centers actively recovering organs from this type of donor has significantly increased the number of organs available for transplantation.[2,118,121-124]

DCD focuses on recovery of the two most commonly needed organs for children: the liver and the kidney. Success with transplantation of DCD organs, primarily the kidney and the liver, is occurring in many centers. Rates of graft survival for some of these organs appear to be similar to that for organs recovered from donors following neurologic death.[125-130] Results from pediatric DCD renal transplants have been acceptable.[118] However, concern has emerged about DCD liver transplantation and an increased risk of biliary stenosis, hepatic infections, postoperative complications, and higher repeat transplantation rates.[8,118,131]

The neonatal donor population is being explored in more detail as another source of valuable organs for transplantation.[132-134] Recovery of neonatal kidneys has the potential to increase the number of kidneys available for transplantation.[8,118,135,136] En bloc renal transplant from neonatal and pediatric DCD donors is also occurring with good success, even in donors as small as 1.9 kg.[136-138] Experience is increasing with lung transplants from DCD donors; however, no children have received lungs from a DCD donor.[139-141] Additionally, the successful transplantation of three hearts recovered from neonatal DCD donors, under an established research protocol, has occurred.[142]

Some controversy exists over this mode of donation. The ethical concerns center primarily on when death occurs and if the potential donor meets criteria for death at the time of organ recovery.[143-147] Although an ethical discussion on DCD donation is beyond the scope of this chapter, many national organizations have reviewed DCD and concluded that this form of donation is ethically acceptable when performed within specific guidelines. The Society of Critical Care Medicine, Institute of Medicine, American Medical Association, American Academy of Pediatrics (AAP), and other medical societies support DCD as an acceptable means to recover organs for transplantation.[3,148-152] The AAP recognizes ethical concerns and encourages but does not mandate physician participation with this type of donation.[153] The AAP does state that institutions should provide access to DCD donation. Education regarding this mode of donation is crucial for all health care personnel to successfully identify and recover organs from this population of children.[7,154,155]

Contraindications to Organ Donation

There are relatively few medical contraindications to organ donation. The transplant surgeon and the medical director of the OPO ultimately determine whether an organ is acceptable for transplantation. This decision is based on the patient's history, laboratory studies, and inspection of organs at the time of recovery. Overwhelming sepsis is usually a contraindication to donation. In many of these cases, most organs

will suffer from inadequate perfusion rendering the organ unacceptable for transplantation. However, patients with meningitis or bacteremia can donate organs if they have been appropriately treated with antibiotics for 24 hours.[8] Other CNS infections such as encephalitis or disseminated viral infections may pose too great a risk to the recipient, limiting the donation potential in these patients. Patients with hepatitis B and C can donate organs to patients who are infected with the same virus. Patients with HIV were once considered ineligible to become donors; however, the HIV Organ Policy Equity Act (HOPE) bill was passed and allows transplantation of HIV-positive organs from a donor with the same serotype. Active malignancies are a contraindication to donation. However, patients who have had cancer and are in remission may be candidates for donation depending on how long they have been in remission. Patients with central nervous system tumors that have not metastasized may be eligible to donate organs. Surgical intervention for these tumors including shunt placement or craniotomy may limit eligibility for donation. Concerns regarding donation potential should be discussed with the OPO medical director before a decision regarding donation eligibility can be established.

Evolving Areas of Transplantation

Improved donor management, operative techniques, postoperative care, and immunosuppressive therapy have advanced transplantation allowing for recovery of more organs and better graft function to meet the growing needs of those waiting for a lifesaving transplant. Uses of organs once considered less than optimal are now being considered for transplantation as technologies develop that can enhance donor organ function. Ex vivo perfusion of donor organs using specially designed organ support systems are being tested to improve the quality of organs prior to transplantation.[156-158] These organ preservation systems specifically designed for the kidney, heart, liver, and lungs may help overcome limitations and effects of cold ischemic preservation that can affect graft performance following transplantation. Ex vivo perfusion can maintain organs in a near physiologic state allowing for longer preservation time for procured organs prior to transplantation.

Infants waiting for a transplant continue to have the highest death rate on the waiting list.[2] Many infants waiting for a heart transplant may die because an organ never becomes available. ABO incompatible heart transplantation and recovery of hearts from neonatal DCD donors may provide needed organs to decrease infant deaths on the national wait list[133,141,159-161] (see also Chapter 39). The use of mechanical support devices can also provide a bridge to heart transplantation. Livers recovered from neonatal donors can undergo special processing for liver cell transfusion under an investigational study.[162] These hepatocytes are being infused into infants with urea cycle defects as a bridge to transplantation.[162,163] Advancement in vascularized composite allograft (VCA) transplantation continues to grow as more experience with face and extremity transplants occurs.[164-166] Vascularized composite allografts have been added under the definition of *organ* in the Organ Procurement Transplantation Network Final Rule.[167]

Summary

The process of organ donation begins when a critically ill or injured child is identified as a potential donor with a timely referral to the OPO. Identifying and caring for the pediatric organ donor requires a skilled team of specialists who deal not only with the deceased child but also with the family. Early involvement of the OPO allows coordination with physicians, social workers, chaplains, and family support services, enhancing the chance for the family to understand and authorize organ donation. Timely and accurate determination of neurologic death allows the focus of medical management to transition toward care and preservation of organs for transplantation once authorization has been obtained. Management of the pediatric organ donor is a natural extension of care for a critically ill or injured child. Meticulous care of the potential donor results in more transplantable organs with improved graft function. Increased numbers of organs recovered from pediatric donors are being transplanted into more children, although adults continue to receive the majority of these organs. The option for organ donation should be made available to every family. Preserving the option of donation provides an opportunity for every family to make decisions about donation when their child has died. Families should be emotionally supported and approached about donation opportunities in a professional, compassionate manner that allows for open discussion during the most difficult, agonizing time in their lives. The positive benefits of donation extend beyond the transplant recipient. Donation helps families heal as they deal with the loss of their child. Collaboration between pediatric critical care specialists, the critical care team, and other dedicated professionals providing specialized donor management can affect the lives of not only the donor family but also the many potential recipients and their families through the effects of a lifesaving and life-changing transplant.

CHAPTER 18

Pediatric Transport

Shifting the Paradigm to Improve Patient Outcome

Kate Felmet, Richard A. Orr, Yong Y. Han, Kimberly R. Roth

PEARLS

- The goal of interfaculty transport is to bring critical care to the patient, providing aggressive stabilization and anticipating the evolution of respiratory failure and cardiovascular instability in a high-risk environment.
- Pathophysiology of acute respiratory and hemodynamic embarrassment in children differs from that in adults in ways that may impact care during transport and make it challenging for multidisciplinary teams to provide excellent care for pediatric patients.
- For most disease processes, speed of transport should not take precedence over providing quality resuscitation.
- Transfer by specialized pediatric transport teams may improve patient outcomes.
- Necessary components of a retrieval system include a communication center, appropriately trained team members, reliable equipment, continuing education, and safety monitoring.
- Although the legal responsibility for safety of interfacility transport rests mostly with the referring facility, the pediatric intensivist who acts as receiving or command physician can play an important role in recommending additional interventions and anticipating the deterioration of pediatric patients en route to tertiary care.

As pediatric emergency and critical care centers have become more regionalized, the need for quality interfacility transport increases. Eighty-nine percent of pediatric emergency department (ED) visits occur in nonpediatric EDs, where the extent of illness or injury is assessed and initial stabilization is provided.[1] Most community hospitals do not have the personnel, space, or facilities to provide critical care to infants or children beyond the period of initial stabilization, necessitating transfer. In

transport, children are subjected to a high-risk environment with limited resources and monitoring capabilities. The goal during transport should be to minimize the risk of deterioration or secondary injury during transport while continuing and, in many cases, advancing the care initiated at the receiving facility.

For most pediatric critical illness, definitive care does not involve miracle drugs or technologies but rather the early, aggressive administration of simple therapies: Timely initiation of resuscitation fluids, inotropes administered via peripheral intravenous line, and antibiotic therapy can improve outcomes.[2,3] If appropriate resuscitation waits until the child arrives in the pediatric intensive care unit (PICU), the benefits of early action may be lost. Goal-directed therapy must begin before and continue during transport for the benefits noted in these studies to occur. Significant barriers to realizing this ideal state exist. A tension exists between the need to transfer patients as rapidly as possible and the desire to make transfers as safe as possible.

This chapter summarizes the physiology relevant to pediatric transport, particularly air transport, with attention to the differences between pediatric and adult patients. It is emphasized that a well-run interfaculty transport team that is focused on the specific needs of children can make a significant difference in patient outcomes. Information about appropriate vehicles, medication, and equipment for transport is best summarized in the American Academy of Pediatrics (AAP) Guidelines for Air and Ground Transport of Neonatal and Pediatric Patients.[4]

Adult-Oriented Medical Systems Frequently Fail Children

In many regions of the United States, medical transport teams that mostly focus on adults, like emergency medical services (EMS) or regional flight teams, are scattered throughout the community, close to referring hospitals, whereas pediatric retrieval teams are located at the sponsoring tertiary care facility. Because they are so accessible to referring hospitals, EMS and regional flight teams transport the majority of critically ill children. Training and protocols of these teams are primarily focused on the major causes of mortality in the adult population, like myocardial infarction, stroke, and trauma, disease processes for which rapid transfer definitive care is an important determinant of outcome.[5] Pediatric intensivists coordinating interfacility transfers need to be aware of the concerns that lead referring physicians to prefer rapid transport by a nonspecialized team over transfer by a team originating at the accepting facility. These concerns are summarized in Box 18.1 and will be discuss in detail throughout the chapter.

Box 18.1

Arguments Against and for Use of Specialized Pediatric Transport Teams

1. Specialized teams take too long to get to the patient.	Concern for bed flow in small referring emergency departments is real, but when we bring goal-directed ICU care to the patient, the time to initiating time sensitive may be shortened.
2. Specialized teams spend too much time on the scene.	Scene time is necessary for stabilization, but the need for additional measures may be underappreciated by the referring hospital.

3. Time to definitive care is longer with specialized teams.	When interventions only available at the accepting facility are the most important determination of outcome, this may be true, but in general, with specialized team, total transport time has not been shown to correlate with negative outcomes.
4. Adult teams have Pediatric Advanced Life Support (PALS) training and can do the same thing.	Nonspecialized teams lack experience with children, are less skilled in assessment of children, and have difficulty maintaining learned skills.
5. Specialized teams are expensive and resource-intensive.	Resource use may be justified by improved outcomes.

Two independent studies reported that as recently as 2003, only 6% of emergency rooms were completely equipped to care for children.[6] In an assessment of the compliance by emergency departments with nationally recognized guidelines on the care of children in EDs, improvements since 2003 were noted, although deficits in equipment and safety procedures remain common.[7] Limited pediatric training coupled with limited exposure to pediatric patients may hamper the ability of ED and EMS providers to respond appropriately to pediatric emergencies. Fewer than 10% of all EMS runs nationwide involve infants and children, and a small percentage of these involve advanced life support (ALS) or critical care.[8,9] Babl and colleagues[10] demonstrated that in a program with 50 active ALS providers, each provider is expected to have one pediatric bag-valve-mask (BVM) case every 1.7 years, one pediatric intubation every 3.3 years, and one intraosseous cannulation every 6.7 years. Without repeated reinforcement, providers' knowledge and skills deteriorate over time.[11,12]

Underutilization of these skills may drive an aversion to performing procedures in children. With any given scenario in the EMS setting, adult patients are more likely to receive an appropriate intervention compared with a child having the same problem.[13-15] Multiple investigators have documented a disconcertingly low percentage of successful intubations in children compared with adult patients.[16-20] Historically, children have been twice as likely to die of trauma in the field compared with adults.[5,21,22] In a retrospective study comparing prehospital intervention of pediatric and adult patients with head injury, paramedics had difficulty with intubation in 69% of children compared with 21% of adults, and they were unable to establish IV access in 34% of children versus 14% of adults.[13]

Referring hospitals that lack pediatric expertise may create suboptimal situations prior to transport. Esposito and colleagues found frequent errors occur in ED management of pediatric trauma, leading to preventable mortality of approximately 9%.[23] They reported a 64% error rate in the management of children, including gross violations of basic trauma care.[23] Han and associates[24] found that resuscitation practice in a community ED was consistent with American College of Critical Care Medicine-Pediatric Advanced Life Support (ACCM-PALS) guidelines in only 30% of children who presented with septic shock. Athey and coworkers[25] found that nearly 10% of all US hospitals without pediatric intensive care facilities admit critically ill and injured children, and that 7% of these hospitals routinely admit these children to adult intensive care units even though most of these lacked appropriate-sized equipment to care for children.[25]

Medical teams that mostly focus on adults often lack the training and the interventional skill to provide excellent initial stabilization. They may also lack an understanding of the physiologic differences between adults and children that impact the changes seen in the first few hours after presentation, the time window in

which most patients are transported. An awareness of these differences will help emergency personnel to anticipate deterioration during transport and choose appropriate interventions before transport.

Critical Pediatric Physiology Relevant to Transport Medicine

Differences between the respiratory mechanics and cardiovascular physiology in adults and children mandate a need for earlier, more aggressive intervention in children with common pediatric problems. Failure to understand these differences can lead to a potentially injurious delay in advanced airway/pulmonary management and shock resuscitation.

Peripheral airway resistance in children younger than 5 years is approximately four times higher than in adults or older children, in whom the upper airway is the major contributor to airflow resistance.[24] For this reason, young children are more likely to have lower airway obstructive disease and are less likely to respond to airway positioning, an intervention that paramedics commonly use to defer intubation in adults.

Infants and small children are at higher risk for respiratory decompensation en route compared with older children adults. Infants and small children have more compliant chest walls with low elastic recoil, increasing the risk of lung collapse.[26] Muscular effort is required to stabilize the chest wall, and a portion of the force of contraction of the diaphragm is wasted in distorting the rib cage.[27] This mechanical disadvantage leads to increased energy expenditure and increases the likelihood that infants with lung disease may fatigue and stop breathing.[28-29] Functional residual capacity is only slightly higher than critical closing volume in infants and small children, leading to alveolar collapse much earlier in the course of respiratory failure. Lung growth appears to involve both an increase in the number of alveoli and an increase in the size of alveolar spaces,[30] which may also predispose the infant lung, with its smaller alveoli, to collapse. In addition, the adult lung contains anatomic channels that allow ventilation distal to an obstructed airway, also known as collateral ventilation; the absence of these pathways in young children further increases the risk for atelectasis.[31] The diffusing capacity across the alveolar-capillary membrane in a child is only about one-third that of an adult, making gas exchange less efficient.[32]

In general, positive pressure breathing applied early in the disease process can stop the progression of atelectasis and respiratory failure. Airway interventions should be planned carefully and performed early in the course of respiratory failure to avoid dealing with a respiratory crisis while en route. Gastric distention can further decrease the efficiency of the diaphragm in children and should be prevented or treated with a nasogastric tube.

Differences in cardiovascular physiology may hamper the ability of providers to recognize shock in children, which may delay the delivery of goal-directed therapy. Infants and children have a greater capacity to increase systemic vascular resistance in shock states and tend to preserve blood pressure until very late in the evolution of shock.[33] Pediatric shock resuscitation protocols developed by the consensus of experts in the field call for treatment of shock using clinical signs, including age-specific targets for heart rate and blood pressure, and relatively subtle indicators of

perfusion as therapeutic endpoints.[34] These subtle signs may be difficult for adult-oriented providers to appreciate. Because children maintain diastolic blood pressure with vasoconstriction and tend to have normal coronary arteries, death from overwhelming shock and myocardial failure is uncommon. This creates the erroneous perception by emergency practitioners that goal-directed therapy is less critical in children and may lead to under-resuscitation.

Stresses of the Transport Environment

The physical stresses of the transport environment do not differ markedly between adults and children but deserve mention here. The transport environment is always risky. Movement of vehicles and ambient noise make examination difficult and monitor function less reliable. Each transfer of the stretcher or isolette from hospital to vehicle or between ambulance and aircraft adds potential for disruption of necessary tubes or devices. Fear and anxiety produced by the transport environment can worsen some conditions; at times it is advantageous to allow a parent to travel with the child. The transport team has to cope with these challenges, relying on only themselves, a limited number of medications, and the equipment they can carry. Depletion of medications and oxygen while en route can be catastrophic.

All of these physical stressors are magnified in air transport. Temperature drops significantly with increasing altitude. Helicopters are not climate controlled. The noise and vibration produced by rotorcraft make auscultation and simple procedures nearly impossible. Flight crews must rely on monitoring that does not depend on audible sounds, such noninvasive blood pressure monitoring, capnometry, and pulse oximetry to monitor patients in flight. Although transport time in a helicopter may be short, physiologic changes are often missed, and new interventions are rarely initiated. For this reason, patients should be well stabilized prior to transport. In particular, the threshold for intubation in pediatric patients undergoing helicopter transport should be lower than in those undergoing ground transport.

Barometric pressure changes associated with increasing cabin altitude lower alveolar oxygen tension and increase the volume of gas entrapped in the bowel, sinuses, pleural space, and so on. At the altitudes used by rotorcraft (generally less than 2000 feet above ground level), changes in oxygen tension are insignificant, and pressure changes have only a minor impact on the volume of air-filled spaces.[35] However, the relatively small volume of air in the tracheal tube cuff may be subject to clinically significant pressure changes at that altitude. A prospective study found that 98% of patients had tracheal tube cuff pressures >30 mm Hg and 72% had intracuff pressures >50 mm Hg during helicopter transport at a mean of 2260 feet.[36] Tracheal tube cuff pressures should be measured and adjusted during flight. Air removed at altitude will need to be replaced during descent.

The United States Federal Aviation Administration regulations mandate cabin altitude less than 8000 feet in fixed wing flight. Most medical flights maintain a cabin pressure equivalent to 6000 to 8000 feet.[37] Atmospheric pressure drops from 760 at sea level to 565 mm Hg O_2 at 8000 feet with a corresponding drop in the partial pressure of oxygen. Predicting PaO_2 at altitude is an inexact science; all that can be said conclusively is that patients with a marginal PaO_2 at ground level will be worse at cruising altitude. In practice, the impact of a cabin pressure in this range can

usually be overcome with supplemental oxygen.[37] Oxygen should be used prophylactically in patients who are sensitive to alveolar hypoxia, like those with reactive pulmonary hypertension.

Ventilators are calibrated for performance at sea level, and those that compensate for changes in barometric pressure do exist but are not in common use. Tidal volumes delivered by the LTV 1000 (Pulmonetic Systems Inc. Minneapolis, MN), a commonly used transport ventilator, may vary from 5% to 12% at a simulated altitude of 4000 and 8000 in volume control mode. At 15,000 feet, LTV delivered tidal volumes may be 30% to 37% greater than set tidal volumes.[38] Similar findings have been reported with the Drager Oxylog ventilator.[38]

Acceleration and deceleration forces during takeoff and landing can cause clinically significant fluid shifts.[37] In most aircraft, the stretcher must be positioned head forward. This position will cause blood to pool in the legs during acceleration or takeoff and in the head during deceleration of landing.[37] In a patient with shock, raising the feet can minimize the decrease in cardiac output due to decreased venous return associated with takeoff. In a patient with increased intracranial pressure, the head should be raised during landing to minimize the increase in intracranial pressure associated with landing in this position.

Rapid Transfer, Goal-Directed Therapy, and the Golden Hour

Adult-focused EMS and regional flight teams operate under the assumption that the time between the moment of injury and arrival at a center capable of delivering definitive care is among the most important determinants of survival. This *golden hour* has been a driving force for clinical decision making since the concept was used to promote helicopter transports for trauma patients in the 1970s, an era when pretransport stabilization rarely went beyond supplemental oxygen[40] (Fig. 18.1). *Scoop and run* remains the prevailing philosophy in the world of adult interfacility transport.

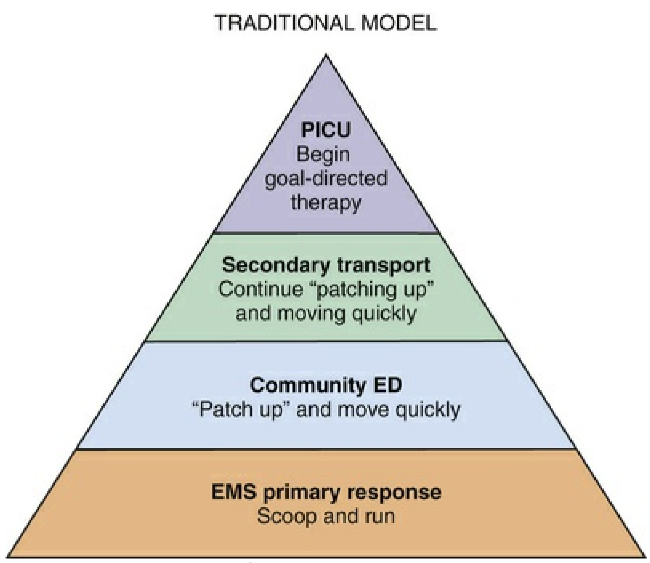

FIG. 18.1 Traditional model of emergency care based on the concept of the "golden hour." *ED*, emergency department; *EMS*, emergency medical

services; *PICU*, pediatric intensive care unit.

There are a few disease processes in children in which rapid transport to a center that can provide definitive care is the most pressing issue. Aneurysms requiring neurosurgical intervention or complete transposition of the great arteries requiring urgent atrial septostomy are examples and are thankfully rare. Respiratory insufficiency and shock are common reasons for referral of pediatric patients. One study identified shock in 37% of children transferred to tertiary centers *regardless of the reason for referral*.[41] It is increasingly recognized that rapid resuscitation is critical to the management of pediatric shock.[34] In adults and children, protocolized, aggressive, early resuscitation of septic shock has proved vastly more effective than any pharmacologic intervention.[2,24,41,42] Aggressive fluid resuscitation and the initiation of inotropes and antibiotics should be accomplished within the first hour after presentation. In adults with septic shock, a delay in antibiotic therapy is associated with worse survival, with mortality increasing by 7% for every 30 minutes that passes without delivery of appropriate antibiotic therapy.[3]

The American College of Critical Care Medicine (ACCM) clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock prescribe simple interventions to be accomplished within the first hour after presentation. Definitive shock resuscitation can be initiated in community EDs and continued and refined in transport, provided that the treating physician and transferring team appreciate the urgent need and are sensitive to the subtle signs of shock in children. Han and colleagues reported that when community physicians aggressively resuscitated and successfully reversed shock before a transport team arrived, patients had a ninefold increase in their odds of survival.[24] These studies defy the popular notion that out-of-hospital stabilization wastes time and delays definitive therapy that should be rendered at the receiving facility. Bringing skilled transport personnel to the child rather than transporting the child with inadequately skilled personnel may markedly decrease the time to effective treatment.

Specialized Teams Improve Outcome

In 1978, Chance and associates[43] demonstrated reduced mortality and more stable physiology in neonates weighing less than 1.5 kg who were transported by a specialized team. Since that time several investigators have reported a decrease in the number of preventable insults in children transported by a pediatric intensive care team compared with a multispecialty team.[44-47] In a study of children transported with head injury, Macnab and colleagues[48] determined that $135,952 in additional costs of care resulted from secondary adverse events occurring during transport by nonspecialized teams. In a prospective cohort study in which allocation of teams depended on team availability, not severity of illness, Orr and colleagues[49] showed that use of a specialized team resulted in decreased severity-adjusted mortality (9% versus 23%) compared with use of a nonspecialized team. Similarly, a large retrospective study of unplanned PICU admissions demonstrated that transfer by a specialty team was associated with improved survival in a multivariable analysis controlling for severity of illness with an odds ratio 0.58 (95% confidence interval [CI] 0.39–0.87).[50]

Pediatric specialized teams often perform additional stabilization maneuvers at

the referring facility, prior to transport. In a prospective observational study, pediatric teams initiated sedation 23% of the time, inotropes 44% of the time, and osmolar therapies for intracranial hypertension nearly 50% of the time when the referring facility had failed to do so.[51] Retrieval teams also imitated mechanical ventilation, acquired central venous access, and placed or adjusted tracheal tubes (Fig. 18.2).[49] Time at the bedside for specialized retrieval teams can be relatively long due to these interventions (in this study, 97 minutes for neonates and 50 minutes for pediatric patients), but scene time has not been associated with mortality.[47]

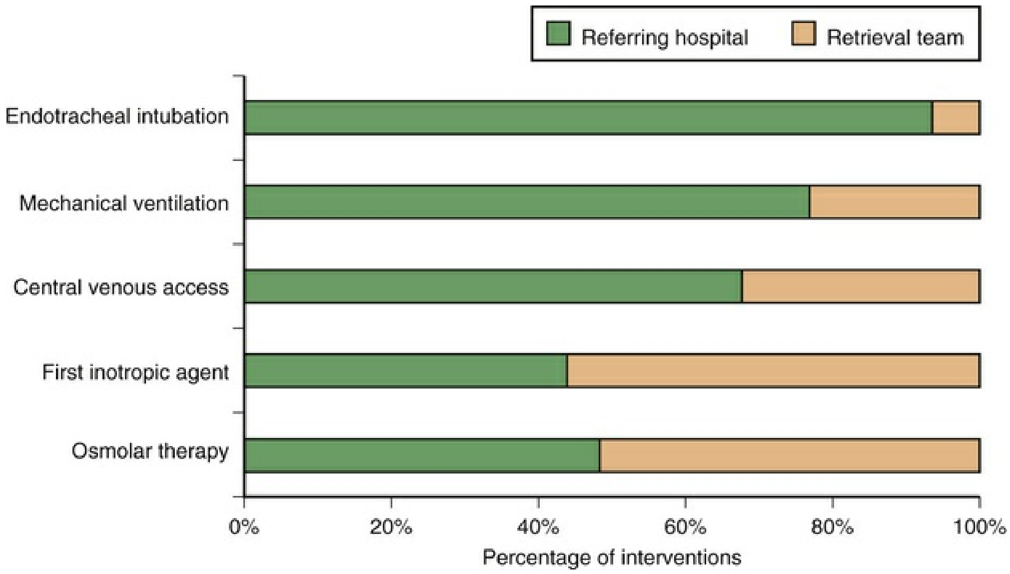

FIG. 18.2 Proportion of interventions performed by referring hospitals and intensive care retrieval teams during stabilization of critically ill children. (From Lampariello S, et al. Stabilisation of critically ill children at the district general hospital prior to intensive care retrieval: a snapshot of current practice. Arch Dis Child. 2010;95:681-685.)

Meaningful stabilization may also continue en route. In a before-and-after intervention trial, introduction of a goal-directed resuscitation protocol (Fig. 18.3) decreased the number of interventions required in the ICU and decreased the hospital length of stay for pediatric patients transported with systemic inflammatory response syndrome (SIRS).[52] In a prospective randomized controlled trial, enhanced monitoring of blood pressure during pediatric interfacility transport resulted in more aggressive resuscitation during transfer, shorter ICU stay, and less organ dysfunction.[53]

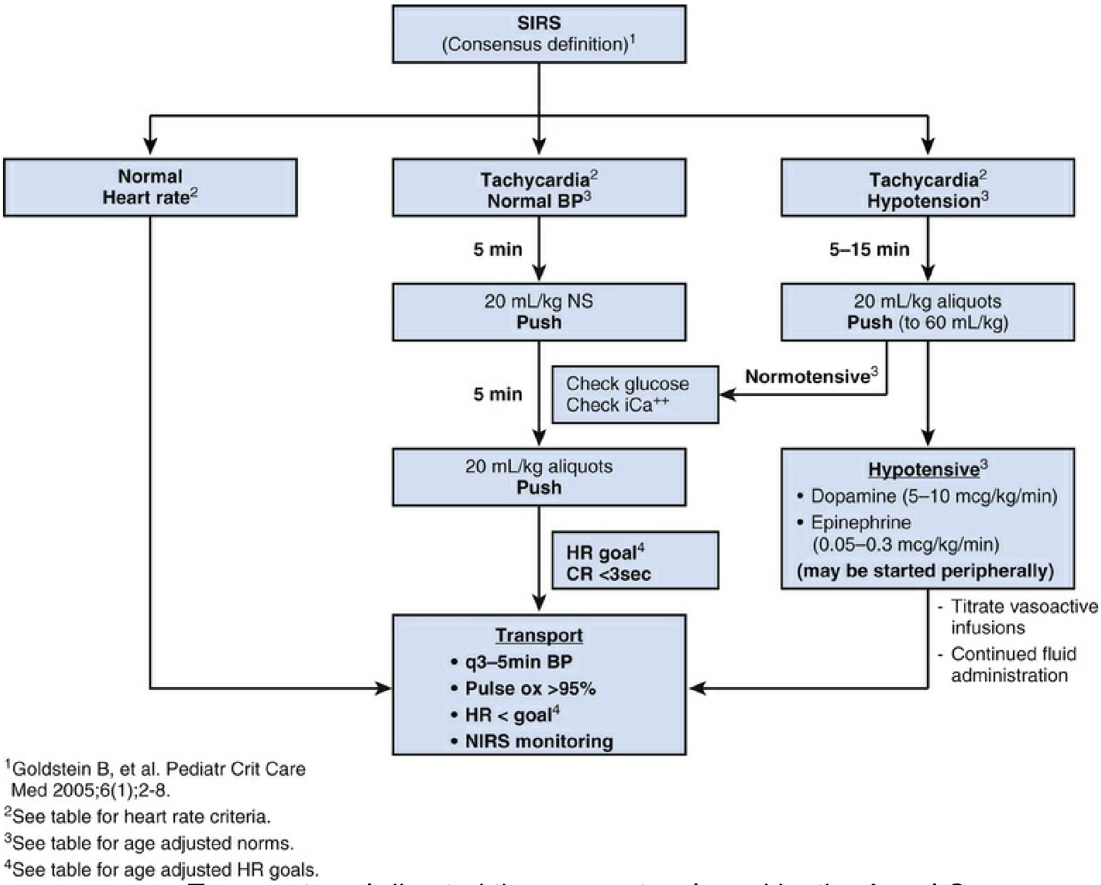

FIG.18.3 Transport goal-directed therapy protocol used by the Angel One Transport team at Arkansas Children's Hospital. *BP*, blood pressure; *CR*, cap refill time; *HR*, heart rate; *NIRS*, near-infrared spectroscopy; *NS*, normal saline; *SIRS*, systemic inflammatory response syndrome. (From Stroud et al. Goal-directed resuscitative interventions during pediatric interfacility transport. Crit Care Med. 2015;43:1692-1698.)

Components of a Specialized Interfacility Transport Team

Pediatric transport is part of a critical care continuum that includes EMS, the referring ED, secondary transfer, and the receiving critical care facility (Fig. 18.4). The continuum is often fragmented, resulting in poor communication, lack of continuity of care, and inadequate quality assessment. An ideal system would provide excellent communication between the referring and receiving hospitals, give clear advice to support the referring staff's care, bring high-level critical care to the patient at the referring institution, and continue optimal care through transport and into the PICU. Ideally, physicians and other caregivers from emergency medicine, neonatology, surgery, and intensive care all take an active role in designing each segment of the continuum and maintaining quality assurance. The critically ill child ultimately will be the responsibility of the pediatric intensivist, so it behooves him or her to have significant input into system design and protocols.

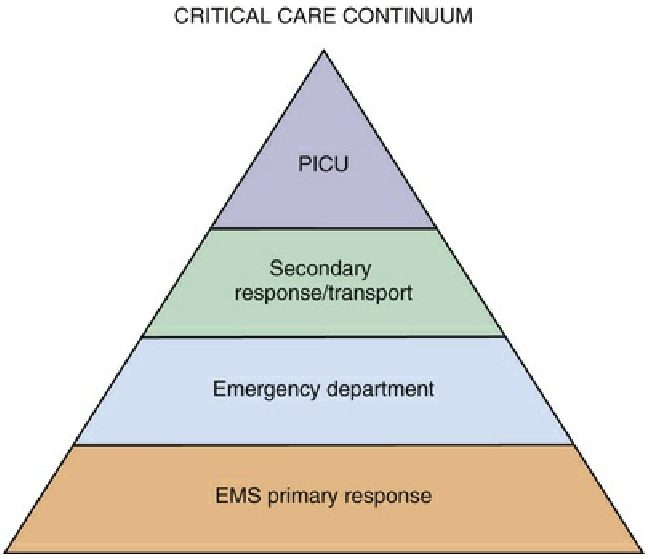

FIG.18.4 Pediatric transport as part of the critical care continuum. *EMS*, emergency medical services; *PICU*, pediatric intensive care unit.

The retrieval system has a responsibility to the referral community to make tertiary care accessible. Differences in topography, weather patterns, and the distribution of hospitals and population centers mean that the ideal transport system will differ from region to region. Regardless, a retrieval system should include a communications center, administrative staff, appropriately trained team members, reliable equipment, and a safety program.

Communications

The communications center should be easily accessible and staffed around the clock by communication specialists who are trained in handling emergency calls and who have no other distracting duties.[54-55] The communication specialist should notify the appropriate personnel and arrange all physical aspects of the transport. Protocols may help to streamline the process and prevent errors. The communication specialist frees the receiving physician and the transport team members to direct their attention to patient care. A detailed log of transport requests, including times, demographic data, diagnosis, and vehicle issues, should be kept for both administrative review and medical-legal documentation. Equipment for direct communication with the center should be available in every transport vehicle. The receiving physician should obtain a brief history of the patient's present illness and a summary of initial interventions and should give recommendations tailored to the capabilities of the referring hospital and pertinent to the current problem. This information should be documented on a log that remains a part of the patient's medical record.

Staffing

The administrative staff of a retrieval system should include, at a minimum, a medical director, transport coordinator, and medical command.[54-55]

The medical director should be a specialist in pediatric or neonatal critical care or emergency medicine. This individual should be experienced in both air and ground

transport (as appropriate to his or her specific system) and should understand patient care capabilities and limitations in the transport environment.

The medical director must be actively involved in quality management, administrative decisions affecting medical care, and the hiring, training, and continuing education of all transport personnel. He or she must orient the physicians who provide online medical direction to the policies, procedures, and patient care protocols and should act as a liaison to the referral community for teaching and outreach.[54-55]

The transport coordinator, usually a nurse or paramedic, collaborates with the medical director with regard to training, protocols, scheduling, data collection, quality management, and marketing. The medical director and transport coordinator should participate in patient transport, whenever possible, to maintain skills and perspective.

A command physician should oversee every transport and provide advice to the referring physician and transport team as necessary. In many cases, the command physician will also be the receiving physician. He or she should be experienced in handling transport calls and offering management suggestions for the period before arrival of the transport team. The command physician should be knowledgeable about the availability of resources and have the authority to accept transferred patients without further consultation, to perform triage, and to activate backup systems when necessary.

Medical control may be online, with direct real-time voice communication between the medical control physician and the transport team, or offline, through written protocols or standing orders for patient management by the transport team. The medical director is responsible for developing and renewing transport protocols and procedures used for offline medical control.

Team composition and training strategies vary considerably among transport programs. A two-person team composed of a nurse and respiratory therapist is the most common configuration for specialized pediatric teams. Selection of team members is critical to the success of a transport program. Members should be selected based on their experience and competence in the care of children in the inpatient setting. Although the specific requirements of training depend on the professional background of the team members, the goals and general content of training are the same for the nurse, respiratory therapist, physician, and paramedic. Transport crew members should be experienced in the care of critically ill patients and be able to deal with complex environments and limited resources. They must be highly skilled in airway management, resuscitation, and vascular access. They should have a fundamental knowledge of field priorities and be able to make decisions independently. All team members should have specific training in transport medicine, which includes methods of functioning in a moving environment, aeromedical physiology, and troubleshooting for equipment-related problems.

The team transporting a critically ill pediatric patient should include a team leader who is experienced in diagnosing and managing life-threatening illnesses or injuries in neonates and children. This caregiver must (1) understand pathophysiology and the usual clinical course and complications of common pediatric illnesses, (2) understand how to use appropriate laboratory and radiographic tests as diagnostic aids, and (3) have experience in managing neonates and children who require

intensive pharmacologic intervention. In order to function independently, the team should be capable of performing, with high level of expertise, all standard emergency procedures required in the care of critically ill neonates and children.

Either an experienced nurse or physician commonly fills the team leader role. Many dedicated pediatric transport teams include a physician, although little objective evidence indicates this configuration improves outcome compared with nonphysician teams. Physician attendance is particularly controversial when the role is filled by physicians in training, as all but the most advanced trainees lack the knowledge and experience needed in the transport environment.

A transport program should define the cognitive knowledge and technical skills required for each professional group and should include a method to document the acquisition and maintenance of these skills. Instruction typically includes didactic sessions designed to assist personnel to acquire cognitive knowledge, a skill development and maintenance program, and a supervised orientation period. Simulation has been shown to improve adherence to protocols in the training of crisis-response teams and may be a useful adjunct to team member training.[56] The supervised orientation period should end only when the training program director and the trainee are confident in the trainee's abilities. A continuing education program must follow and include transport case conferences and review and ongoing competency-based training.

Equipment

For a thorough discussion of transport equipment and options, see the AAP Guidelines for Air and Ground Transport of Neonatal and Pediatric Patients.[4] Equipment taken on transport should be complete and adequate to provide continuing intensive care throughout the trip. Oxygen reserve should be calculated for each patient transported and should be at least twice the amount needed for the expected duration of the trip, in case of delays or equipment malfunction. Portable, compartmentalized equipment packs must be designed for easy access and must be able to withstand the stress of the transport environment. For air medical transport, weight and space restrictions must be considered when selecting equipment and range of medications. Transport monitors should have battery power that will last beyond the expected duration of transport, because of the possibility of unexpected delays or vehicle breakdowns, and should be free of movement artifact. Most important, the transport team should be self-sufficient and not dependent on the referring hospital for supplies. All equipment should be routinely checked and maintained after each transport by a team member dedicated to that task.

Safety

Safety should be a high priority in any transport program. Emergency vehicle operation carries substantial risks, not only to the crew and the patient but also to others in its vicinity. The medical director is responsible for thoroughly researching vendors of air or ground transport services in the areas of maintenance, safety records, experience of drivers and pilots, and reliability of equipment. Written contracts between the institution and the vendor should include specific insurance details. Ambulance drivers should be discouraged from exceeding the speed limit

because no evidence indicates that use of lights and sirens has any positive effect on patient outcome.

Aeromedical transport involves a unique set of safety issues. Pilots who are under pressure to fly or who are sensitive to competition among aeromedical services within a region may fail to observe minimal weather standards, contributing to accidents. Pilots should be isolated from patient care issues to give them the freedom to make sound decisions based on the flight conditions. When aeromedical services compete, they should act jointly to establish regional safety guidelines, minimum weather standards, and a quality assurance program that examines compliance.

The transport team should be adept at survival techniques for their region and should always be prepared to deal with an off-airport landing. Regular sessions to review safety and emergency procedures for each transport mode should be provided for the transport team members.

Referring Hospital Responsibilities

Transfer of patients from one institution to another in the United States is regulated by federal statute. The current legal standard was established by the Consolidated Omnibus Budget Reconciliation Act (COBRA) of 1986 and its amendment in 1989, which created requirements for patient stabilization and transfer, guaranteeing equal access to emergency treatment to all regardless of ability to pay.[57,58] Violations can result in a number of penalties, including termination of Medicare privileges for the physician and hospital. The Emergency Medical Treatment and Labor Act (EMTALA) established by the COBRA legislation further delineates rules for interfacility transfer. Appropriate transfers must meet the following criteria: (1) the transferring hospital must provide care and stabilization within its ability; (2) the referring physician certifies that the medical benefits expected from the transfer outweigh the risks; (3) the patient consents to transfer after being informed of the risks of transfer; (4) the receiving facility must have available space and qualified personnel and agree to accept the transfer; (5) copies of medical records and imaging studies should accompany the patient; and (6) the interfacility transport must be made by qualified personnel with the necessary equipment.

Interfacility transport can be performed by a transport team from the referring facility, by the receiving facility, or by a third party. Under COBRA the referring hospital bears primary responsibility for the safety of interfacility transfer. Ideally, the decision about choice of team and mode of transport would be made jointly between the referring and receiving physicians. Physician-to-physician communication should include the following: (1) identification of the patient and medical history, (2) interventions performed during initial stabilization and patient's response, (3) pertinent physical examination findings, (4) ongoing therapy, and (5) potential complications that may occur during transport.

Summary

The limited pediatric training and exposure of EMS personnel, coupled with the differences in size, anatomy, physiology, and psychosocial aspects unique to children, will continually challenge the EMS provider. The approach that prioritizes

rapidity of transport over stabilization and initiation of care, a pattern that is commonly accepted for adult patients, will not result in the best outcomes for most children. The need for pediatric-specific intensive care begins long before the patient arrives in the tertiary care center. Children transported by nonspecialized teams are at higher risk of transport-related adverse events and mortality. The primary goals in the majority of pediatric transports should be anticipatory management of respiratory insufficiency and early and attentive application of the principles of goal-directed shock resuscitation. Most pediatric patients with septic shock survive their acute illnesses, and emergency providers rarely witness the development of organ dysfunction in the first few hours of the shock state. The unique perspective of the pediatric intensivist is valuable and can help to change practice in the referring community.

CHAPTER 19

Pediatric Vascular Access and Centeses

Sanjiv Pasala, Elizabeth A. Storm, Michael H. Stroud, Punkaj Gupta, Nahed El-Hassan, Thomas J. Lee, Olivia K. Irby, Xiomara Garcia-Casal, Stephen M. Schexnayder

PEARLS

- Intraosseous infusion is a convenient means of emergency vascular access with new mechanical devices available. Vigilant observation of the needle insertion site is necessary to recognize extravasation and prevent serious complications.
- Pericardiocentesis may be required for both diagnostic and therapeutic purposes. Ultrasound imaging improves success and reduces complications, and it should be employed in all cases except with life-threatening tamponade.
- Umbilical arterial and venous access may be useful in neonates up to 2 weeks of age.

Intraosseous Infusion

Venous access in critically ill infants and children can be one of the most challenging aspects of their care. Peripheral veins in infants can be difficult to cannulate, particularly in the event of shock with shunting of blood away from the periphery and collapse of small veins. Because of these challenges, intraosseous (IO) infusion has become widely accepted as a quick, reliable means to establish short-term emergency venous access.[1,2]

IO infusion was first described in 1922 and became widely used in the 1930s and 1940s.[3] With the development of disposable needles and catheters, use of IO infusion fell out of favor. It was not commonly used again until the mid-1980s, when a series of publications demonstrated the utility of the technique for rapid venous access in critically ill children.[4,5]

The marrow space provides a noncollapsible access point to the vascular system. Marrow sinusoids drain into medullary venous channels that empty into the systemic circulatory system. Because of the noncollapsible nature of the marrow space and the direct connection to the venous circulation, fluids and medications infused into the marrow space are distributed rapidly through the venous

circulation.

Indications

IO infusion is indicated in situations requiring the rapid acquisition of intravenous (IV) access in which the establishment of conventional peripheral access is difficult or impossible. The situations in which it is most often used include cardiopulmonary arrest, shock, burns, and status epilepticus. In these situations, limited attempts at standard peripheral access are usually made prior to placing an IO needle. In addition to its use in the hospital, IO access has been used successfully in the prehospital setting as well as in critical care transport.[6-8]

The success rate with the technique is high, greater than 95% with experienced practitioners.[9] Equal success using the newer mechanical intraosseous devices has also been demonstrated with equivalent pharmacokinetics.[10,11] Most fluids and medications that can be given through a conventional IV line can be given via an IO infusion with comparable results. In the event of cardiac arrest or severe shock, IO access is at least as effective as peripheral venous access in providing fluids and medications to the central circulation. Studies have shown that commonly used resuscitation, antiepileptic, and antibiotic drugs can be given effectively through an IO line. Three antibiotics produce subtherapeutic levels when given via an intraosseous line at standard IV doses: chloramphenicol, vancomycin, and tobramycin.[12]

In addition to the administration of fluids and medications, IO access can be used for certain clinical laboratory studies. No significant differences were found when comparing electrolytes, chemistries, pH, PCO_2, or hemoglobin from IO marrow specimens with either arterial or venous blood samples.[13] A marrow specimen can be cultured in lieu of a blood culture.[14] Finally, the marrow can be used for blood type and cross-matching.

Contraindications

IO infusion has few absolute contraindications. A fractured or previously punctured bone should not be used because infused fluid will extravasate and possibly cause compartment syndrome. Alternate sites in other bones can be used in such situations. Bone diseases such as osteogenesis imperfecta and osteopetrosis have been suggested as contraindications to intraosseous infusion.[15] Placing the needle into an area of cellulitis or burn could cause osteomyelitis or other infectious complications and is a relative contraindication, although if limited sites are available, placing the IO needle through burned skin is acceptable.

Supplies and Equipment

Bone marrow space is accessed with the use of one of several different types of needles. Conventional bone marrow needles (eg, Jamshidi needle, CareFusion, San Diego, California) work well. Needles made specifically for IO infusion use are available, including a straight needle or a needle with a threaded screw device (eg, Sur-Fast, Cook Medical, Bloomington, Indiana). Usually a 15- or 18-gauge needle is chosen. The smaller 18-gauge should be used in infants. Studies have shown no

significant differences in time required to insert the needle, success rate, or extravasation rates between standard and threaded IO needles.[16,17] If bone marrow or IO needles are not available, standard lumbar puncture needles can be used,[9,18] although they are prone to bend. In neonates, even a 19- or 21-gauge butterfly needle can be used.[18] Needles with a stylet are preferred to prevent clogging of the needle by bone.

Two mechanical devices appropriate for the pediatric population have been introduced: the Bone Injection Gun (B.I.G., Waismed Ltd., Herzliya, Israel) and the EZ-IO (Vidacare Corporation, San Antonio, Texas; Figs. 19.1 and 19.2). The B.I.G. is a spring-loaded device, whereas the EZ-IO is a small battery-powered drill; both penetrate the bone marrow more quickly as compared to the manual method and are used more frequently than manual IO placement in many settings, including prehospital.[19] In addition, FAST1 (Chinook Medical Gear), a sternal injection gun, is used in the adult population but will not be discussed here.

FIG. 19.1 Bone injection gun. (Courtesy Persys Medial and Waismed USA.)

FIG. 19.2 EZ-IO. (Courtesy Vidacare Corporation.)

Other equipment required for IO placement includes a towel or sandbag, syringes with saline or heparinized saline flush solution, IV fluid and tubing, a T-connector or stopcock, and antiseptic prep solution (iodine). Optional supplies include a pressure bag and materials for local anesthesia (syringe with 25-gauge needle and 1% lidocaine).

Technique

The IO needle can be placed into the bone marrow at one of several sites, including the proximal tibia, distal femur, distal tibia, iliac crest, and sternum. The proximal tibia is the site most commonly chosen. The sternum has been used in adults but should be avoided in children because of the possibility of perforating the smaller chest cavity. In addition, placing the needle in the sternum can interfere with airway and circulatory resuscitative efforts. When the needle is placed in the proximal tibia, the insertion site is located by palpation on the flat anterior tibial surface 1 to 3 cm (two fingers breadth) distal to the tibial tuberosity (Fig. 19.3). This site is chosen to avoid the proximal growth plate. The midshaft should not be used because of increased risk for fracture. Placing a towel or sandbag under the child's leg helps stabilize the leg and makes insertion easier. The skin overlying the area should be prepped with antiseptic solution. Local anesthesia by infiltration with 1% lidocaine should be performed if the patient is awake. If a needle with a plastic sheath is being used, adjust the sheath so that an adequate length of needle protrudes beyond the sheath. Some authors have suggested inserting the needle at a 60- to 75-degree angle away from the tibial growth plate, but others recommend using a perpendicular or 90-degree angle. The perpendicular angle helps prevent the needle from sliding along the bone. The needle is advanced using firm pressure and a twisting or rotary motion until a “give” or loss of resistance is felt, indicating entry into the marrow space. The force needed to penetrate the bony cortex is considerable; the twisting motion helps significantly in needle insertion. One disadvantage of using a threaded needle is that the “give” or loss of resistance that occurs when the needle enters the marrow space may not be felt; however, the needle may be more secure in the bone

once the needle is placed.[20]

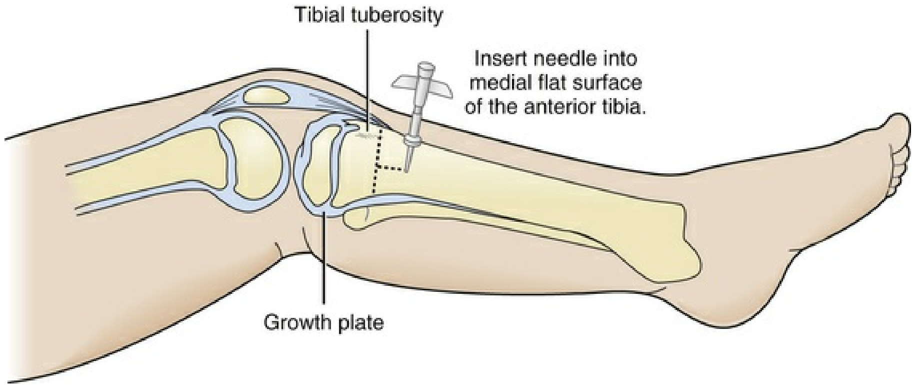

FIG. 19.3 Insertion of the intraosseous needle into the anterior tibia.

The stylet is removed and a syringe is attached to the needle to attempt to aspirate marrow. Correct placement of the needle should be confirmed to avoid extravasation. Aspiration of bloody fluid into the syringe confirms that the needle is correctly placed. Additional evidence of correct needle placement includes the observation that the needle stands upright in the bone without support and lack of resistance when flush solution is infused into the needle with the syringe. Sometimes marrow cannot be aspirated even if the needle is correctly placed. If the "give" is felt on insertion and the needle stands alone in the bone but marrow cannot be aspirated, infusion of a small amount of fluid with the syringe can be attempted. Fluid should infuse easily with little pressure and without noticeable swelling of the soft tissues or extravasation of fluid.

Placement of IO needles with the newer mechanical devices has success rates equal to or higher than traditional manual methods, with the added benefit of ease of use and less risk to the user.[7,10] However, the high cost of this equipment may be a major limitation for use, especially in small facilities or resource-limited settings. In children, prehospital providers preferred the IO drill to the spring-loaded injection gun.[20,21]

When using the spring-loaded injection gun, after choosing the desired needle depth of penetration by dialing to the patient's age, the B.I.G. is positioned over the desired site with one hand while the other hand squeezes and pulls out the safety latch. The free hand is then used to activate the device at a 90-degree angle to the surface. The device is removed by pulling upward with a slight side movement to clear the needle. The stylet trocar is pulled out, then the safety latch should be slid over the needle and the apparatus taped as necessary for stabilization.

When using the IO drill, the operator must first ensure that driver and needle set are securely seated. After removing and discarding the needle set safety cap from the IO needle, the operator positions the driver at the insertion site with the needle set at a 90-degree angle to the bone and gently powers or presses the needle set until the needle set tip touches bone. At least 5 mm of the catheter must be visible. The bone cortex is penetrated by squeezing the driver's trigger and applying gentle, steady downward pressure. The trigger should be released when a sudden "give" or "pop" is felt upon entry into the medullary space and a desired depth is obtained. If excessive force is used, the driver may stall and not penetrate the bone. Gentle

pressure and catheter tip rotation will provide the necessary penetrating action. After placement, the power driver and stylet are removed and catheter stability confirmed. A primed extension set is then attached to the catheter hub's Luer-Lok and the apparatus is flushed. The manufacturer does not recommend attaching a syringe directly to the IO needle hub, to reduce the risk of needle dislocation.

The possible insertion sites are the same whether using the manual or mechanical needles. When the needle is placed in the distal femur, it should be positioned approximately 2 to 3 cm proximal to the patella in the midline. In the distal tibia, the needle is placed 1 cm proximal to the medial malleolus midway between the anterior and posterior surfaces, posterior to the saphenous vein. The proximal tibia is usually selected in children younger than 4 years, but the distal tibia has been recommended in older children in whom the proximal tibial cortex is thicker. The proximal humerus can also be used, with the insertion site 1 to 2 cm proximal to the surgical neck of the humerus.

Maintenance

Once correct placement of the needle is confirmed, fluids and medication can be administered with a syringe via a stopcock or T-connector, or a standard IV infusion set can be connected to the needle. The needle is secured using gauze pads and tape. Some have suggested taping a clear plastic cup over the needle to help prevent dislodgment.[9] The site should be observed visually and by palpation for signs of extravasation, both immediately after placement and frequently (every 5 to 10 minutes) during use. If evidence of extravasation is seen, the needle should be removed to avoid compartment syndrome. If needle placement is attempted at one site and the cortex is penetrated but the line cannot be used because of extravasation, another bone must be chosen for subsequent attempts.

IO access is intended only for short-term use in emergency resuscitative situations; long-term use increases the risk of extravasation, compartment syndrome, and infection.[22,23] Therefore once IO access is secured, efforts should be directed toward obtaining conventional IV access. Once alternate access is obtained, the IO needle should be removed, manual pressure applied for 5 minutes, and a dressing applied to the site.

Complications

Significant complications of IO infusion are rare. The most common complication is extravasation of fluid. The causes of extravasation include incomplete penetration of the bony cortex, movement of the needle such that the hole is larger than the needle, dislodgment of the needle, penetration of the posterior cortex, and leakage of fluid through another hole in the bone, such as a previous IO site or fracture. Extravasation of a small amount of fluid is usually not problematic, but compartment syndrome may result after extravasation of larger volumes of fluid. Use of the IO line for prolonged periods and use of the IO line with pressure infusion appear to be risk factors for compartment syndrome. Compartment syndrome associated with IO infusion can result in the need for fasciotomy and amputation. Careful frequent observation of the IO site is necessary to detect extravasation and to prevent compartment syndrome. If extravasation occurs, the

needle should be removed and the extremity observed for signs of compartment syndrome. Initial experience suggests the complications of the new mechanical devices are similar to that for the traditional IO needle.

Other rare complications include infection and bone fracture. Osteomyelitis, cellulitis, and sepsis have been reported in conjunction with IO infusion.[24] Risk for infection is increased when IO access is used in a bacteremic patient and when the line is used for a prolonged period. The risk of osteomyelitis is low. Although IO access is usually obtained in emergency situations, precautions to prevent infection should be taken, including use of sterile gloves and equipment and preparation of the skin with antiseptic solution (iodine or alcohol). Fracture of the bone has been reported.[25]

Summary

IO infusion is a valuable means of obtaining temporary, emergency vascular access in the critically ill infant or child. It has a high success rate and is associated with rare complications. Using appropriate technique and vigilantly monitoring the site for extravasation can usually prevent complications.

Arterial Catheter Placement

Frequent access to arterial blood is essential for a complete and thorough assessment of acid-base status, oxygenation, and ventilation in the critically ill patient. The dynamic, often rapidly evolving nature of critical illness in children, including the potential for rapidly changing hemodynamic status, routinely requires continuous measurement of blood pressure as an invaluable tool in planning timely interventions aimed at improving systemic oxygen delivery. Since the 1970s, arterial catheter placement in critically ill children has allowed continuous measurement of systolic, diastolic, and mean blood pressure, and it provides a visible pressure waveform that may contribute additional diagnostic information (see also Chapters 28 and 29). It also provides direct access to arterial blood for frequent, painless sampling. Hence the ability to place an arterial catheter is a fundamental skill in pediatric critical care medicine.

Indications

Indications for an arterial catheter include the following:

1. Need for frequent measurement of blood pressure to assess the patient's hemodynamic status and to allow for timely assessment of interventions aimed at improving hemodynamic status, such as fluid administration and titration of vasoactive infusions.

2. Need for frequent sampling of arterial blood for laboratory analysis. Access to arterial blood through an indwelling catheter increases the ease of painlessly obtaining blood samples for analysis. Obtaining arterial samples through a catheter also eliminates skewing of results by physiologic changes related to the stress of arterial puncture or venipuncture, such as increased respirations with crying,

localized poor perfusion, or tourniquet use. Most notably, an indwelling arterial catheter allows for frequent assessment of arterial blood gas measurements, thereby providing the most accurate information on a patient's acid-base status, as well as measurement of PaO_2.

3. Need for continuous monitoring of cerebral perfusion pressure (CPP) in patients with traumatic brain injury or other causes of increased intracranial pressure (ICP) (see also Chapter 62).

4. Need for arterial access to facilitate therapeutic procedures, such as exchange transfusions and continuous arteriovenous hemodiafiltration.

Contraindications

Few absolute contraindications for placement of an arterial catheter exist. The skin at the site of arterial access must be intact prior to insertion of a catheter. Evidence of infection of the skin or underlying structures is a contraindication to catheter placement at this site. Other disruptions in skin integrity, such as burns, are a relative contraindication. Severe coagulopathy and systemic anticoagulation increase the risk of hemorrhage from unsuccessful arterial punctures associated with attempted arterial catheter placement, as well as the risks of bleeding at the site of arterial catheter insertion. These risks must be weighed against the potential benefits of improved monitoring when deciding to place an arterial catheter in a coagulopathic or anticoagulated patient.

A catheter should not be placed in an extremity with compromised perfusion. Evidence of adequate collateral circulation is desirable prior to placement of an arterial catheter. The traditional means of assessing collateral circulation to the hand is the Allen test. The radial and ulnar arteries are compressed until the distal extremity is blanched. Pressure over one artery then is released and capillary refill should return to the distal extremity in less than 5 seconds. The test is repeated releasing pressure over the other contributing artery. However, a normal Allen test does not guarantee adequate collateral circulation, nor does an abnormal test necessarily indicate possible complications.[26] The Allen test is considered less reliable for patients in shock. Additionally, an arterial catheter is often placed without assessing collateral circulation in emergent circumstances.

Procedure

Box 19.1 lists the supplies and equipment required for arterial catheterization.

Box 19.1

Supplies and Equipment for Arterial Catheterization

1. Appropriate size catheter (24 gauge for infants, 22 gauge for toddlers and older)

2. Sterile gloves

3. 10% povidone-iodine or chlorhexidine solution

4. Sterile towels

5. Syringe with 1% lidocaine and 25-gauge needle for local infiltration

6. Topical anesthetic cream

7. Luer-Lok connector with heparinized flush

8. 3-0 silk suture

9. Instrument tray with needle holder and scissors

. Cloth tape

. Plastic, nonocclusive dressing

. Connecting tubing

. Transducer

. Fluids containing heparin (1 unit/mL) and papaverine

Technique

The initial step in placing an arterial catheter is site selection. The radial, posterior tibial, and dorsalis pedis arteries are optimal sites, due to easy accessibility and typically good collateral circulation. Placement of the catheter in distal arteries of the extremities also allows for ease of site observation and hemorrhage control with direct pressure. Preductal placement in the right radial artery is preferred in infants with ductal-dependent heart lesions.

Catheters also can be placed in the axillary or femoral arteries if no peripheral sites are suitable. Insertion of a catheter into the axillary artery is technically more difficult than the other sites mentioned and is associated with a risk of brachial plexus injury due to hematoma compressing the neurovascular bundle.[27] Traditionally, many physicians have been reluctant to place arterial catheters for long-term use into the femoral artery, particularly in infants and young children, for fear of complications, most notably severe ischemia of the limb. A retrospective study of 234 pediatric burn patients who underwent 745 femoral artery catheterizations revealed a 1.1% rate of loss of distal pulse. In this retrospective study, limb ischemia was associated with younger age, smaller patient size, and increased severity of the burn injury. Patients who suffered limb ischemia were managed with immediate catheter removal and systemic heparinization. Three underwent thrombectomy, with one requiring amputation of a digit.[28] Traditional teaching has held that the brachial arteries should not be used for arterial catheters because of the lack of collateral blood flow and risk of distal extremity ischemia. In a review of arterial catheter placements performed at a pediatric cardiac surgical center, 386 brachial artery catheters were placed in infants weighing 20 kg or less

with no report of permanent ischemic damage and only three with temporary perfusion loss.[29] Despite these results, the complete lack of collateral circulation at the brachial artery requires careful consideration of risks and benefits before placement of a brachial artery catheter. Additionally, the superficial temporal arteries should not be used due to poor collateral flow and the possibility of retrograde flow resulting in showering of emboli into the cerebral circulation.

The selected site must be properly immobilized prior to placement of the indwelling catheter. If placing a radial artery catheter, the wrist is hyperextended 30 degrees to develop a straighter course and more superficial position of the radial artery. Typically, the radial pulse is best palpated in a position just proximal to the proximal wrist crease. The technique for radial arterial catheter placement has been expertly summarized in the "Videos in Clinical Medicine" series in the *New England Journal of Medicine*.[30]

Arterial catheter placement at any site is performed by initially preparing the site with a chlorhexidine solution and draping it with sterile towels. Lidocaine (1% without epinephrine) is infiltrated locally. Alternatively, lidocaine/prilocaine (EMLA) cream can be used as a local anesthetic. Systemic narcotics or anxiolytics may be administered, although cautiously in patients not receiving mechanically ventilation. Percutaneous placement of the catheter can be accomplished using one of several techniques. In the over-the-needle technique, similar to placement of a peripheral IV catheter, the needle is inserted through the skin at a 30-degree angle (bevel up or down). When a flashback of blood is obtained in the hub, the catheter is advanced another 1 to 2 mm. While the needle is held stable, the catheter is advanced over the needle into the lumen of the vessel. Blood should be flowing continuously into the catheter hub prior to attempting to advance the catheter. Once the catheter is inserted through the skin to the hub, pressure is applied over the artery proximal to the catheter and a flushed Luer-Lok connector is attached to the hub. Correct placement of the catheter is verified by easily aspirating arterial blood into a syringe. The catheter is then flushed and securely sutured or taped into position. A transparent dressing is placed over the catheter as a protective barrier, usually after placement of a chlorhexidine-impregnated patch at the site of catheter insertion to decrease catheter-associated bloodstream infections.[31]

Transfixation, the second percutaneous technique, involves using the over-the-needle technique; however, when a flashback of blood is seen in the hub, the needle and catheter are further advanced through the posterior wall of the artery and this wall is transfixed to the underlying structures. The needle is pulled out, leaving the catheter in place. The catheter is then slowly withdrawn until the tip is again intraluminal, with blood flowing back into the hub. The catheter is then advanced into the artery up to the hub. Catheter advancement can be facilitated by attaching a syringe filled with flush to a connecter and gently flushing as the catheter is advanced. The position of the catheter is confirmed, and the catheter is secured as described earlier.

The final and most successful percutaneous method for catheter placement in critically ill patients involves use of the Seldinger technique.[32] A needle is used to pierce the anterior wall of the artery, and when return of arterial blood is seen, a guidewire is placed through the introducer needle and advanced into the lumen of the artery. The needle is then removed, and a catheter is advanced over the guidewire into the lumen of the vessel. This method also can be used with the over-

the-needle technique. A study in pediatric patients showed improved success rates and time to insertion when arterial catheters are placed using a wire guide compared to no wire guide.[33] However, an adult study found no difference between wire guide versus no wire guide success rate or insertion times.[34] When placing a catheter into larger vessels such as the femoral artery, using the Seldinger technique, a longer catheter (eg, 5-8 cm) should be used.

Interest continues to grow in ultrasound-assisted placement of arterial catheters (see also Chapter 20). Studies have demonstrated decreased time to insertion and decreased number of attempts at catheter placement using ultrasound-guided compared to pulse palpation techniques.[35-37] However, a large randomized trial of pediatric patients receiving radial arterial catheter placement via ultrasound-guided versus traditional techniques by pediatric subspecialty trainees or anesthesiologists with minimal ultrasound experience found no difference in success rate.[38] A cutdown approach serves as an alternative if percutaneous attempts are unsuccessful. A superficial incision of the skin is made perpendicular to the artery. The subcutaneous tissues are bluntly dissected parallel to the vessel using hemostats. When the artery is identified, the posterior wall is gently dissected away from the adjacent structures. Two loops are placed around the vessel: one proximal and one distal. These loops are used to elevate the artery during cannulations; they should never be used to tie off the vessel. The artery is then cannulated under direct visualization using the over-the-needle technique. The catheter is secured with a suture through the skin, and the wound is closed with interrupted stitches. If excessive bleeding persists, gentle traction can be applied to the proximal loop in an attempt to control the hemorrhage.

Maintenance of an Arterial Catheter

To prolong patency of an arterial catheter, heparinized fluid is most commonly infused through the catheter. A common practice is to infuse 0.9% sodium chloride containing heparin 1 unit/mL at 3 mL/hr, although slower infusion rates may occasionally be used in small infants with a need for fluid restriction. There is conflicting literature supporting the use of heparin to positively impact patency and the risk of clot formation in peripheral arterial catheters.[39,40] However, more recent adult studies call into question the benefit of heparin and the need for more rigorous clinical investigation.[41,42] These studies do not take into account the smaller vessel size and prolonged monitoring common in critically ill children. A randomized, controlled trial of the addition of papaverine (60 mg/500 mL) to routine arterial catheter fluids demonstrated a significantly lower rate of catheter failure and longer catheter life in the papaverine group.[43] This study recommended avoiding the use of papaverine in neonates due to a perceived increased risk of intraventricular hemorrhage (IVH); however, a more recent study of neonates 25 to 36 weeks gestational age showed no increased risk of IVH.[44] Despite these results, many institutions routinely avoid the use of papaverine in arterial catheter fluids in preterm neonates and in patients with traumatic brain injury or some other preexisting intracranial hemorrhage.

The arterial catheter should always be visible so any bleeding around the catheter site or an inadvertent disconnection of the tubing from the catheter can be immediately observed to avoid significant hemorrhage. Securing the catheter with

suture and the use of Luer-Lok connectors decreases the possibility of accidental detachment. The site of catheter insertion should be closely monitored for signs of infection or compromised perfusion. Mottling of the skin proximal or distal to the catheter may be indicative of intraarterial thrombus formation, and discoloration of fingers or toes distal to a catheter may result from emboli. The catheter must be removed if any of these complications are observed. Children with femoral artery catheters are at a higher risk of thrombus formation, and those of newborn age, lower body weight, low cardiac output, and elevated hematocrit have an even higher risk of femoral artery thrombosis.[45]

Arterial catheter transduction is performed with the transducer located as close as possible to the level of the right atrium and zeroed to atmospheric pressure for accurate measurements.[46] Studies in animal models have demonstrated that positioning the transducer level with the aortic root results in accurate measurement of mean arterial pressure regardless of patient position or catheter site, whereas placement of the transducer level with the catheter tip resulted in significant error in mean arterial pressure measurement.[47] Currently, changing arterial line fluids and tubing is recommended to occur every 96 hours.[48] The overlying dressing also is changed on a scheduled basis.

Inability to draw blood from a catheter or flattening of the waveform on the monitor is suggestive of either a kinked catheter or thrombus formation at the end of the catheter. If no evidence of compromised perfusion is present distal to the catheter, changing the catheter over a guidewire may be considered. However, strong consideration should be given to removing the existing catheter and placing another arterial catheter in a new position, as changing a catheter over a guidewire has been associated with an increased risk of catheter-associated bloodstream infection (CABSI), at least in central venous catheters.[49]

Complications

Complications related to arterial catheters include hemorrhage, thrombus formation, emboli, distal ischemia, and infection. Permanent ischemic complications related to radial artery catheters in adult patients are rare events.[27] A multiinstitutional diagnostic code database study demonstrated 10.3% of patients with arterial catheters also had a code associated with infection or inflammation and 7.5% had a thrombotic or embolic associated complication code. These complications were more common in younger children and those with longer hospitalizations.[50] In addition to bleeding, infection, and distal limb ischemia, an uncommon but well-recognized complication of arterial catheter placement is growth arrest due to physeal injury from extravasation, aneurysm formation, or ischemia.[51]

Catheter-related infections can be local or the focus for systemic sepsis. The risk of catheter-related infection has previously been thought to be lower for arterial catheters than for central venous catheters; however, a meta-analysis indicated arterial catheters are an underrecognized source of CABSI.[52] The risk of arterial catheter infection has been related to the duration of catheter use and to placement of a catheter in the femoral artery.[53-55] Presence of an arterial catheter has been noted to be a risk for CABSI, but it has been suggested that it is more likely that a positive culture is a surrogate marker for greater illness severity.[56] Regardless, the arterial catheter should be considered a possible source of sepsis, and strong consideration

should be given to removing an arterial catheter when it is no longer necessary for optimal care.

Summary

Arterial catheterization is a necessary skill for the pediatric intensivist for the routine monitoring of many critically ill children. The potential risks and benefits of arterial catheter placement should be carefully weighed prior to the procedure. Rigorous studies investigating the complications associated with arterial catheterization are lacking for critically ill children, and further study is needed.[50]

Pericardiocentesis

Pericardiocentesis is the aspiration of fluid or air from the pericardial space. Pericardiocentesis can be performed emergently without imaging guidance techniques; however, this should only be undertaken in dire circumstances because of the risk of the procedure and the higher failure rate when no guidance is used.

Indications

Drainage of a pericardial effusion of any cause is absolutely indicated when cardiac tamponade is present. Often drainage is recommended if the effusion is large, even in the absence of tamponade, for diagnosis and fluid removal.[57] For small effusions, pericardiocentesis may be indicated for diagnosis alone. In pediatric patients, pericardial effusions most commonly occur with postviral or idiopathic pericarditis, but they are also seen with postpericardiotomy syndrome, collagen vascular disease, oncologic disease, and, rarely, uremia.[57] Purulent pericarditis resulting from *Staphylococcus aureus* or *Streptococcus pneumoniae* infection can be seen in cases of concomitant pneumonia with empyema. Although rare in developed countries, tuberculous pericarditis can occur. Drainage of purulent pericarditis is indicated for relief of tamponade, prevention of constrictive pericarditis, diagnosis, and drainage of infection. With purulent pericarditis, open drainage may be more effective because of the difficulty in draining thick pus.[58] If using a tube for pericardiocentesis and drainage, instillation of a fibrinolytic agent such as alteplase (recombinant tissue plasminogen factor) may be considered with purulent effusions. Traumatic pericardial effusions secondary to penetrating trauma often require surgical drainage of the blood, because tamponade is common. Pneumopericardium secondary to pulmonary air leaks in mechanically ventilated patients is usually well tolerated hemodynamically but may require drainage, especially in small infants, because of the development of tamponade.

Contraindications

There is no absolute contraindication to pericardiocentesis in an emergency situation. The presence of aortic dissection or myocardial rupture is considered a major contraindication. The presence of a bleeding diathesis or coagulopathy is another contraindication. Open drainage is preferred to closed drainage when the patient has traumatic tamponade and is in cardiac arrest. When the effusion is

loculated in a location not easily reached using the subxiphoid approach, needle pericardiocentesis is contraindicated because the risk of complications increases and the possibility of successful drainage is low.

Procedure

Drainage of a pericardial effusion can be performed either by simple needle aspiration or by insertion of a drainage catheter. If the procedure is for diagnosis only and the effusion is small, then needle drainage is adequate. However, if tamponade is present, the effusion is sizable, or effusion likely will continue, insertion of a catheter for continuous drainage is indicated.

Equipment

1. *Needles for drainage* range in size from 14 to 20 gauge, depending on the type of fluid and the size of the patient. For thicker fluids, such as pus or blood, a larger-bore needle is used. A steel needle, such as a vascular introducer needle or a spinal needle, can be used, but often an IV catheter is more effective because once the fluid is reached, the steel inner needle can be removed from the IV catheter, leaving the softer, needleless catheter in place while the fluid is aspirated. This process decreases the risk of cardiac puncture.

2. *Syringes, three-way stopcock, and short extension tubing* are assembled for aspiration. A 5- or 10-mL slip-tip syringe is used when accessing the pericardium for easier manipulation. A larger 20- to 30-mL syringe may be needed for fluid drainage, depending on the predicted volume. The stopcock and short tubing are useful when draining large amounts of fluid.

3. *Equipment for insertion* includes 2% chlorhexidine solution, sterile gloves and drapes, and 1% lidocaine for local anesthesia.

4. Appropriate *sterile sample tubes* should be available for collection of fluid for chemical, cellular, and microbiologic analysis.

5. A *cardiac monitor* is essential for determining arrhythmias during the procedure.

6. *Catheter, dilator, and flexible J-wire* are necessary when the catheter will be left in place. Placement in the pericardial sac of a 5- to 8-Fr pigtail catheter with multiple side holes is recommended. The size of the patient and the viscosity of the fluid determine the size of the catheter. If the fluid is fibrinous in appearance by echocardiography, then a larger-bore catheter should be placed. Several pigtail catheters are manufactured specifically for fluid drainage, often available as kits that also contain an appropriate-size dilator and J-wire guide. If a kit is not available, then a venous dilator of appropriate size with a separate J-wire can be used. A J-wire is used to prevent another puncture of the pericardium or heart using a straight wire. Before the needle is inserted, the wire, dilator, and catheter must be checked to ensure their sizes are compatible.

Monitoring for Pericardiocentesis

Monitor all critically ill patients continuously with both pulse oximetry and electrocardiograph (ECG) monitoring. Before pericardiocentesis, provide airway and respiratory support as clinically indicated. Procedures such as rapid sequence intubation or positive pressure ventilation can precipitate a sudden decrease in preload leading to acute events such as cardiac arrest. Monitoring the ECG tracing while advancing the pericardiocentesis needle enables the clinician to detect needle contact with the epicardium, which helps prevent cardiac puncture.

Echocardiographic guidance is recommended for most pericardiocentesis because it can be done at the bedside and is logistically less complex.[59] Echocardiographic scanning is indicated prior to needle drainage or catheter insertion for any reason except tamponade with cardiac arrest. The echocardiogram can show the size of the effusion, its distribution around the heart including any loculations, the presence of fibrin or clots, and evidence of tamponade. Tamponade can be diagnosed using two-dimensional imaging when the right atrium collapses during late diastole.

Technique

Needle aspiration can be performed blindly in the event of a true emergency such as traumatic tamponade; however, the technique has higher complication and failure rates. Among the potential chest sites for pericardiocentesis in infants and children, the subxiphoid approach is the safest and most common approach, although other approaches have been described. The approach is extrapleural and, in patients with normal anatomy, avoids major vessels such as the internal mammary, coronary, and pericardial arteries.[57] The subxiphoid and lower costal margin are prepared with 2% chlorhexidine. The area is draped in a sterile fashion. Lidocaine local anesthesia is infiltrated at the junction of the xiphoid and the left costal margin. The needle is inserted at a 30- to 45-degree angle and directed toward the left clavicle (Fig. 19.4). The slip-tip syringe is attached and is aspirated continually while the needle is inserted (Fig. 19.5). Needle advancement is halted when air or fluid is aspirated. During insertion the needle is guided using two-dimensional echocardiography. The echocardiographic probe is placed on the chest where the fluid is best seen. The needle tip is identified by ultrasound and followed as the needle is advanced.[60] Another technique involves mounting the needle on the echocardiographic probe, which has been placed in a sterile sleeve. The needle is advanced while the operator also handles the probe. This technique allows the use of locations other than the subxiphoid approach for insertion of the introducer needle, with the potential for better fluid visualization.[61] After the fluid has been echocardiographically evaluated, the patient is placed supine with the head elevated approximately 30 degrees.

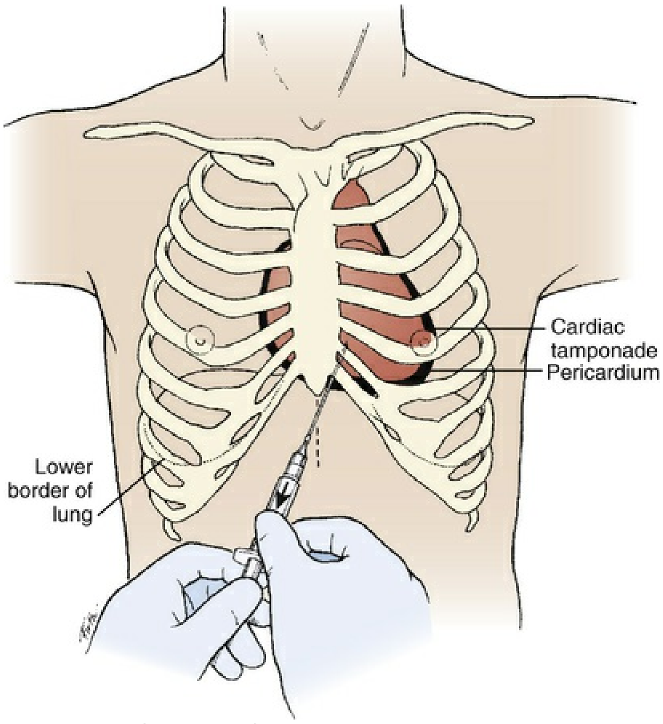

FIG. 19.4 Insertion of needle for pericardiocentesis at the junction of the xiphoid and the left costal margin, aiming toward the left shoulder. (From Brundage SI, Scott BG, Karmy-Jones R et al. Pericardiocentesis and pericardial window. In Shoemaker WC, Velmahos GC, Demetriades D, eds. Procedures and Monitoring for the Critically Ill. Philadelphia: Saunders Elsevier; 2002.)

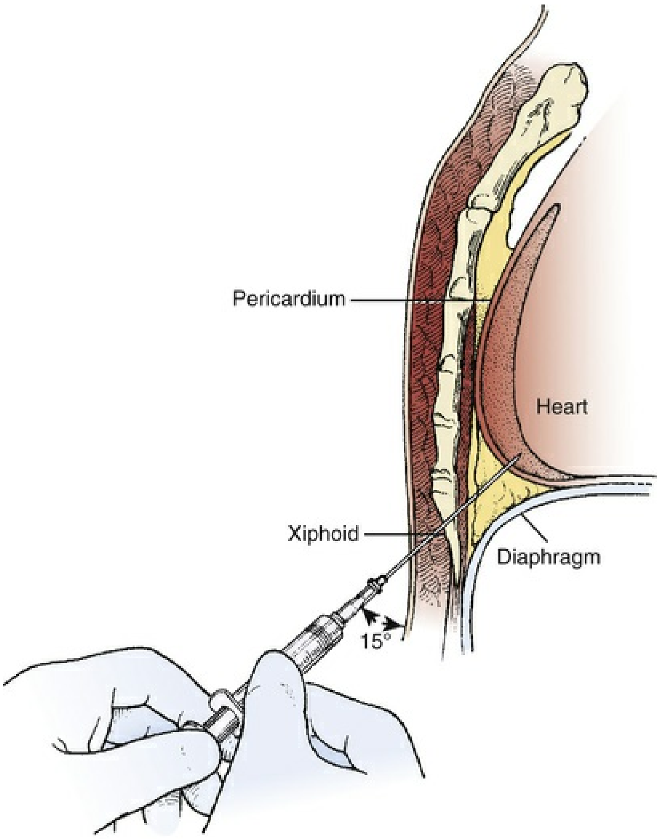

FIG. 19.5 In pericardiocentesis, the needle is inserted slowly, under continuous aspiration, toward the heart at a 15-degree angle to the skin. (From Brundage SI, Scott BG, Karmy-Jones R et al. Pericardiocentesis and pericardial window. In Shoemaker WC, Velmahos GC, Demetriades D, eds. Procedures and Monitoring for the Critically Ill. Philadelphia: Saunders Elsevier; 2002.)

If blood is obtained, analysis is necessary to determine whether the blood is of pericardial or intracardiac origin. Several techniques are helpful for this determination. The hematocrit of pericardial fluid will be lower than that of intracardiac blood, which will be equal to the patient's hematocrit. Dropping a few milliliters of the fluid on gauze sponges determines whether the fluid will clot. Fluid that does not clot is pericardial; fluid that does clot is most likely intracardiac blood. Another technique involves injection of small amounts of saline microbubble contrast (saline in a syringe that has been agitated) through the introducer needle while imaging with echocardiography. If contrast bubbles are seen in the heart, then the tip of the needle is intracardiac or intravascular. If bubbles appear in the pericardial sac, then the needle is appropriately placed in the pericardium.

Once the needle is determined to be well positioned in the pericardial sac, if a catheter is to be inserted, then the J-wire can be passed through the needle as with standard Seldinger technique. The needle is removed, and the dilator is passed over the wire to open the tissues outside the pericardium and enlarge the puncture in the pericardium. The dilator is removed, taking care to leave the J-wire in good position. The catheter is passed over the wire into the pericardial sac. Its position can be confirmed echocardiographically. The wire is removed. The connecting tubing and three-way stopcock are connected and the fluid is aspirated. The tubing can be connected to a drainage bag for removal of fluid that continues to accumulate. A sterile sample of the aspirated fluid should be sent to the laboratory for appropriate analysis. The catheter is secured with suture and covered with an occlusive dressing. A chest radiogram should be taken at the end of the procedure and daily to confirm the catheter position.

Maintenance

The catheter is simple to maintain. The dressing should be changed according to the ICU protocol for central venous lines. The fluid in the drainage bag should be measured and the amount recorded on a regular schedule. If fluid is no longer draining, then a small amount (1 to 2 mL) of heparinized saline can be infused into the pericardium through the stopcock after preparation with antiseptic solution. This process can release any fibrinous material occluding the catheter. If no fluid is forthcoming, then echocardiography can be performed to determine if residual pericardial fluid remains. If more fluid is present, flush the catheter again in an attempt to open up the catheter. If the fluid had originally been purulent, then instillation of a fibrinolytic agent may allow better drainage. If no fluid remains, the catheter can be removed, depending on the patient's condition and the underlying cause of fluid development.

Complications

The most serious and immediate mechanical complications of pericardiocentesis are

myocardial puncture or laceration, vascular injury (coronary, intercostal, internal mammary, or intraabdominal), pneumothorax, air embolism, and arrhythmia (ventricular and supraventricular). Coronary laceration occurs rarely, resulting in acute myocardial ischemia. Transperitoneal needle passage can traverse intraabdominal organs. The liver is most commonly involved but is associated with low risk of significant hemorrhage. Perforation of a hollow viscus is theoretically possible but rarely reported. Infection of the indwelling catheter can occur but is rare because the catheter is not in place for more than 3 to 4 days.

Summary

Pericardiocentesis, with or without catheter placement, is a straightforward procedure that is indicated for relief of cardiac tamponade and for a diagnosis of certain pericardial effusions. It is a lifesaving technique for patients with tamponade. Patients needing emergency pericardiocentesis are checked with pulse oximetry and ECG monitors. Used in conjunction with guidance techniques such as echocardiography or electrocardiography, pericardiocentesis can be performed safely in patients of all ages.

Umbilical Arterial Catheter and Umbilical Venous Catheter Placement

Umbilical vein cannulation was first described in 1947 for an exchange transfusion in an infant with severe indirect hyperbilirubinemia.[62] Umbilical artery cannulation was later described in 1959 for blood gas sampling.[62] Since the early 2000s, umbilical arterial catheter (UAC) and umbilical venous catheter (UVC) placement have become routine procedures in the neonatal intensive unit (NICU).[63] UAC is indicated for frequent blood sampling, continuous measurement of blood pressure, and exchange transfusion.[63,64] UVC is needed for administration of fluids, parenteral nutrition, and blood products.[63,64] However, the advantages of these lines must be carefully balanced against the potential risks.[65,66] Several life-threatening complications have been associated with the use of these catheters.[65,66]

Supplies and Equipment

Prepackaged umbilical catheter insertion trays are commercially available and contain different sizes of catheters. The 3.5F and 5F are the most frequently used catheters.[63,64] Umbilical catheters are typically made of polyvinylchloride and have a single end hole, as side hole catheters have been linked with higher incidence of thrombosis.[67,68] Umbilical catheters are available as single or multiple lumens. A single lumen can be used in either vessel, whereas a double- or triple-lumen catheter is used exclusively in the umbilical vein.[69] More than one lumen allows the administration of incompatible fluids. A 3.5F catheter is utilized for infants weighing <1500 g, and a 5F catheter is used for larger infants.[63,64]

Technique

The infant is kept in a supine position by using soft restraints of the arms and legs or

via a swaddling technique. A catheter is prepared for insertion by connecting to a Luer-Lok stopcock and flushing with saline, with or without heparin. The umbilical stump and surrounding skin are thoroughly cleansed with 2% chlorhexidine or providone-iodine.[63,70] The antiseptic agent is allowed to dry and is then removed with sterile saline. The area is draped, sparing the head and chest to allow for appropriate patient monitoring. A cord tie is applied around the umbilical stump. Using a scalpel, the cord is horizontally cut 1 to 2 cm above the umbilical ring.[70] The larger, single thin-walled umbilical vein is typically located at 12 o'clock, whereas the two thick-walled generally constricted umbilical arteries are identified at 5 and 7 o'clock.[70] A single umbilical artery is sometimes isolated and can be a normal variation.[63,70]

I Umbilical Arterial Cannulation

Once the umbilical artery is identified, the iris forceps is used to gently dilate the arterial lumen by first inserting the forceps in the closed position and subsequently allowing both prongs to spring open and dilate the lumen.[63,64] The catheter is introduced 0.5 cm in the lumen of the vessel.[63,64] Thereafter, the umbilical cord is pulled toward the infant's head before further introducing the catheter. The direction of the catheter advancement is caudal.[71] The catheter enters the umbilical artery, passes through the internal iliac artery, the common iliac artery, and finally the descending aorta.[71] Resistance to catheter advancement is occasionally encountered secondary to vasospasm, at the junction of the umbilical artery and facial plane, or at the level of the bladder. Gentle pressure can be applied. Sometimes the catheter can cross the wall of the umbilical artery creating a false lumen. A double-catheter technique can then be attempted.[72] The first misdirected catheter follows a path of least resistance. A second catheter is also used to bypass this pathway and then enters the aorta.[72] If this technique fails, the second umbilical artery is cannulated. The patency of the catheter is verified by adequate blood return and flushing. The catheter is sutured in place, using a purse string stitch cinched tightly to provide hemostasis and wrapping both ends of the suture around the catheter before tying a square knot. The line is secured using a tape bridge or other available securing device.[73] The umbilical tie is loosened and kept in place for any needed hemostasis. A transducer can be attached for continuous blood pressure monitoring while still allowing blood sampling.[74]

Two depths of UAC insertion are described in the literature.[75-77] Low or high placement of the catheter is based on the vertebral level at which the catheter resides in the aorta.[71,75-77] Low placement is defined as the catheter tip caudal to the origins of the renal arteries, whereas a high placement is described as the catheter tip in the descending aorta above the diaphragm and below the left subclavian artery.[71,75-77] A Cochrane review evaluated the effects of the position of UACs and concluded that high-placed catheters led to fewer clinical vascular complications.[78] Although reference charts based on patient morphometric are available, there are simple formulas that predict the depth of insertion of arterial catheter.[75-77] Shukla's regression equation based on birth weight (BW) predicts UAC insertion length (cm) as (3 × BW (kg) + 9) for infants weighing ≥1500 g, whereas Wright's formula (4 × BW (kg) + 7) results in more accurate UAC placement (cm) for infants weighing <1500 g.[76,77]

II Umbilical Venous Cannulation

Once the umbilical vein is identified, a catheter is introduced carefully in the lumen.[63,64,70] The umbilical vein does not always require routine dilation prior to the introduction of the catheter.[63,64,70] The umbilical cord is gently pulled toward the feet during placement to straighten the course of the vein. The direction of the catheter advancement is cephalad.[63,64,70] A properly placed UVC enters the inferior vena cava and the right atrium through the umbilical vein and the ductus venosus.[79] Sometimes, the catheter is misdirected into the portal, the splenic, or the mesenteric vein.[79] If there is resistance to insertion or poor blood return, inappropriate position of the catheter should be suspected. The double-catheter technique, described in the UAC section, can also be used in UVC placement.[79] The patency of the catheter is then verified by adequate blood return and flushing. The line is secured using the same technique described in the UAC paragraph.[63,64,70]

The length of catheter insertion is determined by the size of the infant and the indication for placement.[63,76,79] In emergency situations, the catheter is advanced to a depth where rapid blood return is achieved (2 to 4 cm in most infants).[63,75,76] A long-term UVC resides at the junction of the inferior vena cava and right atrium.[63,75,76] The two most commonly used methods to predict accurate depth of UVC are nomograms based on the measurement of the shoulder-umbilicus length and regressions equations based on BW.[75,76] Shukla's formula, $([3 \times \text{BW (kg)} + 9]/2) + 1$, is widely used to estimate the length of UVC insertion (cm).[76] Verheij suggested that Shukla's formula leads to over insertion of catheters and recommended a revised formula, $[3 \times \text{BW (kg)} + 9]/2$.[80]

Proper Placement of Umbilical Arterial and Venous Catheters

Anteroposterior and lateral views of a thoracoabdominal radiograph are required to confirm proper placement of the catheters.[81] Low UAC placement correlates with the third and fourth lumbar vertebrae on chest film, whereas a high placement correlates with the sixth and tenth thoracic vertebrae.[81] UVC tip should be positioned at or just above the diaphragm or between the eighth to tenth vertebrae.[81] Several studies have questioned the optimal diagnostic approach to determine the correct position of the umbilical catheters.[81] Questions were raised on the difficulty of relating anatomic structures to the projection of vertebral bodies on x-ray secondary to the variability of these structures in relation to bony landmarks. Bedside ultrasonography is suggested as a better modality for verifying the position of the umbilical catheters.[81] However, the disadvantage of this technique is the constant need for qualified personnel to perform the study at the time of the catheter's placement.[81] Due to this limitation, most centers still rely on radiography to assess the catheter's position.

Maintenance

Infants are typically placed in the supine position or on their sides.[63,64,70] A dressing should not be applied to the umbilicus so that the catheter insertion site can be easily inspected.[63,64,70] The UVC is maintained as part of a closed system to prevent air embolism. A continuous infusion is needed to keep the lumen of the UAC clear, and the catheter is flushed after blood draws to minimize clot formation. Continuous

fluid infusion containing heparin is needed in the arterial line.[82] The composition of the heparin-containing fluid varies by institution and is influenced by gestational age and electrolyte status. A typical infusion includes 38 to 77 mEq/L sodium chloride or sodium acetate or an isotonic amino acid solution with heparin 1 unit/mL.[82,83]

Removal

Umbilical line catheters are removed one at a time. Each catheter is pulled to approximately 5 cm, then the catheter is slowly withdrawn in increments of 1 cm/min.[84] This process is especially important during the removal of UACs because it allows the artery to spasm and provide hemostasis. If bleeding occurs, pressure is applied by elevating and pinching the skin just above the cord for venous bleeding or below the cord for arterial bleeding.[84] A hemostat can also be used to pinch the lumen of the vessel for persistent bleeding.[63,84]

Complications

Umbilical venous and arterial cannulations are associated with potential complications. These complications are related to placement and malposition of the catheters or prolonged catheter placement in the umbilical vessel.

Umbilical Arterial Cannulation

Several complications are linked to UAC placement and catheter tip position. Trauma to the vessel leading to hemorrhage can occur during placement.[85,86] Vasospasm of the umbilical artery with resulting blanching or cyanosis of the toes, feet, or buttocks has been described.[85,86] Warming of the unaffected limb may improve perfusion of the other extremity. Otherwise, catheter removal is warranted to prevent ischemic complication.[85,86] Other complications are peritoneal perforation, bladder injury, breaks of catheters, intravascular knots of catheters, or catheterization of the urachus resulting in urinary ascites.[64,85,86]

Additional complications can develop with prolonged indwelling of the UAC. McAdams and colleagues investigated the effects of UAC placement in an animal model and concluded that thrombus formation was detected in 80% of aortic sections.[87] In addition, the incidence of developing aortic thrombus increases proportionally to the duration of UAC placement and has been reported as 16% within 1 day, 32% within 7 days, and 80% within 21 days of UAC placement.[87] The presentation of emboli ranges from asymptomatic to limb-threatening ischemia or mesenteric artery occlusion with necrotizing enterocolitis or renal artery occlusion with renal failure and hypertension.[64,85-87] Furthermore, once the intima of the vessel has been traumatized, the vessel becomes susceptible to infection. In most instances, the microorganisms are coagulase negative staphylococci. These pathogens produce a biofilm that preferentially adheres to irregular catheter surfaces.[88] Catheter-related infection may also cause aortic aneurysm.[66] The Centers for Disease Control and Prevention (CDC) reaffirmed in 2011 that UACs should be removed as soon as possible and ideally should not be kept longer than 5 days.[88] It further states that UACs should be removed if signs of vascular insufficiency occur.[88]

Umbilical Venous Cannulation

A common complication of UVC placement is catheter tip malposition. A low positioned UVC within the confluence of the portal circulation may precipitate hepatic injury.[65] Clinical features of liver complications vary and can be asymptomatic or present as abdominal distension with hepatomegaly, hypotension, worsening respiratory status, or portal thrombosis with chronic portal hypertension.[65] A catheter tip in the right atrium can also result in pericardial effusion and tamponade.[89]

Complications related to UVCs indwelling over time include sepsis and thrombosis.[90] Both risks increase when the catheter is left in place for prolonged periods of time. Multiple interventions are recommended to prevent central line–associated bloodstream infection and include limiting central line access for injecting medications, enforcing *scrub the hub* before accessing the central line, and replacing UVCs as soon as possible with peripherally inserted central catheters (PICCs).[88] In 2011, the CDC recommended "removal of UVCs as soon as possible when no longer needed but UVCs can be used up to 14 days if managed aseptically."[88] Interestingly, Butler-O'Hara and colleagues completed a randomized controlled trial that showed similar infection rates with UVCs left in place up to 28 days compared to UVCs replaced by PICCs after 7 to 10 days.[91] However, the same authors later published a quality improvement project revealing a greater risk of infection with long-term compared to short-term UVC followed by PICC placement.[92] The authors hypothesized that the substantial decrease in PICC infection rates in their unit altered the risk-benefit ratios between the two strategies (short and long term) of UVC use.[92]

Summary

Umbilical lines are commonly used in the care of severely ill neonates. The use of UACs for blood collection and blood pressure monitoring and the use of UVCs for nutrition or medications have become commonplace in NICUs and can also be used in the pediatric intensive care unit (PICU). Although there are several benefits to their use, umbilical catheters are associated with potential problems. An awareness of the possible complications is important to minimize serious consequences and provide timely interventions.

Central Venous Line Placement

Central venous line (CVL) placement and use are frequently required in caring for critically ill patients. The need for central access should be anticipated so that circumstances surrounding the procedure, such as sterile technique and the patient's safety and comfort, can be optimized.

Indications and Contraindications

Indications for CVLs include the following:

- The need for reliable and durable venous access
- A lack of or inadequate peripheral venous access
- Administration of vasoactive infusions, total parenteral nutrition, and medications

that require central venous delivery

- Frequent blood sampling
- Monitoring of central venous pressure and central venous oxygen saturation
- The need to provide access for extracorporeal support modalities such as continuous renal replacement therapy and apheresis

Contraindications to central access are not absolute and are primarily related to catheter placement at specific sites. In the presence of increased bleeding risk, sites where bleeding may be difficult to control, such as the subclavian, should be avoided if possible. In patients with significant intraabdominal or pelvic trauma, femoral catheters may pose increased risk. Bacteremia present at the time of catheter placement likely will colonize to central venous catheters. Catheters should not be inserted through obviously infected skin. The relative risk and benefit of catheter placement should be carefully considered before each procedure.[93]

Technique

Critically ill pediatric patients vary greatly in size, and the pediatric intensivist should have an awareness regarding the dimensions of the vein that is being accessed and the proximity and anatomic relation of the respective artery to the vein. The diameters of the central veins vary across the pediatric age groups (Table 19.1).

TABLE 19.1

Approximate Mean Femoral and Internal Jugular Vein Diameter Across the Pediatric Age Period

Age	Mean IJV Diameter (mm)	Mean FV Diameter (mm)
25-27 weeks PCA[a]	2.1	1.5
31-33 weeks PCA[a]	3.3	1.9
37-39 weeks PCA[a]	4.2	2.3
1 month	5.5[b]	4.5[c]
1 year	6.2[b]	5.4[c]
2 years[d]	6.7	6.3
4 years[d]	7.8	7
6 years[d]	8.9	7.7
8 years[d]	10	8.5
10 years[d]	11.1	9.2
13 years[d]	12.8	10.4
16 years[d]	14.5	11.5
19 years[d]	16.2	12.6

Appropriate-sized catheters for CVL placement in pediatric patients should be

readily available. These catheters are commonly plastic polymer and available in a variety of diameters, lumen numbers, and lengths. They can be packaged with appropriate-sized introducer needles, guidewires, and tissue dilators, along with other necessary equipment such as local anesthetic, skin cleanser, drapes, and suture for securing the catheter.

Adequate sedation and analgesia plus local anesthesia should be used not only to provide patient comfort during the procedure but also to make the procedure easier and safer with less patient movement.

Full barrier precautions should be used whenever a CVL is placed in the PICU and should include hair cover, mask, careful handwashing, sterile gown and gloves, a large area of skin prepped with antiseptic solution, and a draped sterile field large enough to eliminate the possibility of inadvertent contamination of equipment and sterile surfaces. Chlorhexidine is superior to povidone-iodine for skin disinfection.[94]

The majority of CVLs employed in the PICU are placed using the Seldinger technique. The technique is essentially the same regardless of the site used. The clinician places an introducer needle into the desired vein while aspirating with a syringe. When the lumen of the needle is fully within the lumen of the vein, blood flows freely into the syringe. The needle should be held in place with one hand while the syringe is disconnected with the other hand. The rate at which blood passively flows from the open needle hub depends on the gauge of the needle and the venous pressure; however, it should not be obviously pulsatile. A J-tipped guidewire is inserted into the open hub of the needle and advanced into the vein (Fig. 19.6A). The wire should meet little or no resistance as it is advanced. If resistance is met, attempts to advance the wire should cease. The position of the needle should be adjusted by either advancing or withdrawing slightly or changing the angle of entry. The wire can be carefully withdrawn and the syringe reattached to the needle in order to reidentify the lumen of the vein. If resistance is met while withdrawing the wire, the needle and wire should be withdrawn as a unit rather than risk breaking or cutting the wire. Once the guidewire is well within the lumen of the vein, a small incision is made adjacent to the needle to enlarge the puncture site to more easily accommodate the dilator and catheter. Next, the introducer needle is carefully withdrawn along the wire, holding the wire completely stationary. A dilator of appropriate size is advanced along the wire into the puncture far enough to dilate all tissue planes into the lumen of the vein. The dilator is withdrawn, and the desired catheter is advanced into position along the wire (Fig. 19.6B). The guidewire is removed, leaving the catheter in place. Blood should be easily aspirated from all lumens. Each lumen should be filled with sterile saline or heparinized saline to prevent thrombosis.

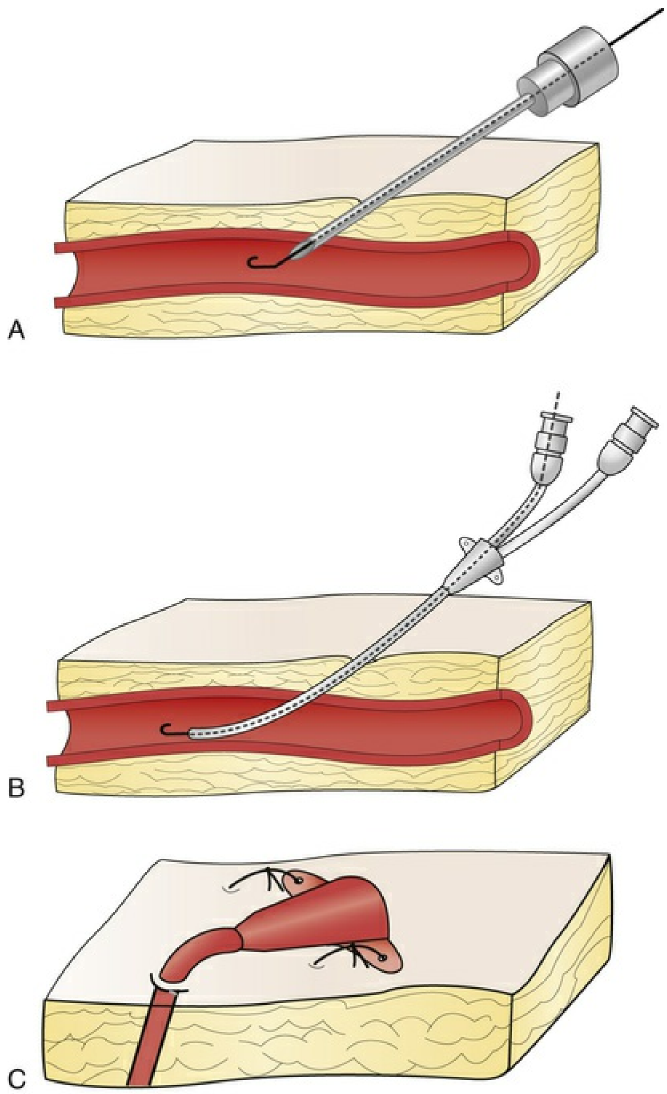

FIG. 19.6 (A) Guidewire is placed through the introducer needle into the lumen of the vein. (B) Catheter is advanced into the vein lumen along the guidewire. (C) Hub of the catheter is secured to the skin with suture.

Several systems for securing catheters are commercially available. The most common technique uses silk suture. A large loop of suture should be placed in the skin, attached through the wings of the catheter hub, and tied tightly enough to prevent catheter movement but not so tightly as to cause necrosis of the skin within the loop of suture material (Fig. 19.6C).

Internal Jugular Vein Cannulation

Multiple approaches can be used to cannulate the internal jugular vein. For each of these approaches, the patient is supine in slight Trendelenburg position, with a roll of bed linen under the shoulders to extend the neck and with the face turned to the contralateral side. The middle or low approach is most commonly used (Fig. 19.7A). The introducer needle enters the skin at the apex of the triangle formed by the clavicle and the heads of the sternocleidomastoid muscle at a 30-degree angle to the skin directed toward the ipsilateral nipple. For the anterior approach, the introducer needle enters the skin along the anterior margin of the sternocleidomastoid halfway

between the mastoid process and the sternum and is directed at the ipsilateral nipple (Fig. 19.7B). Using the posterior approach, the needle enters the skin along the posterior border of the sternocleidomastoid halfway between the mastoid process and the clavicle and is directed toward the suprasternal notch (Fig. 19.7C).[95]

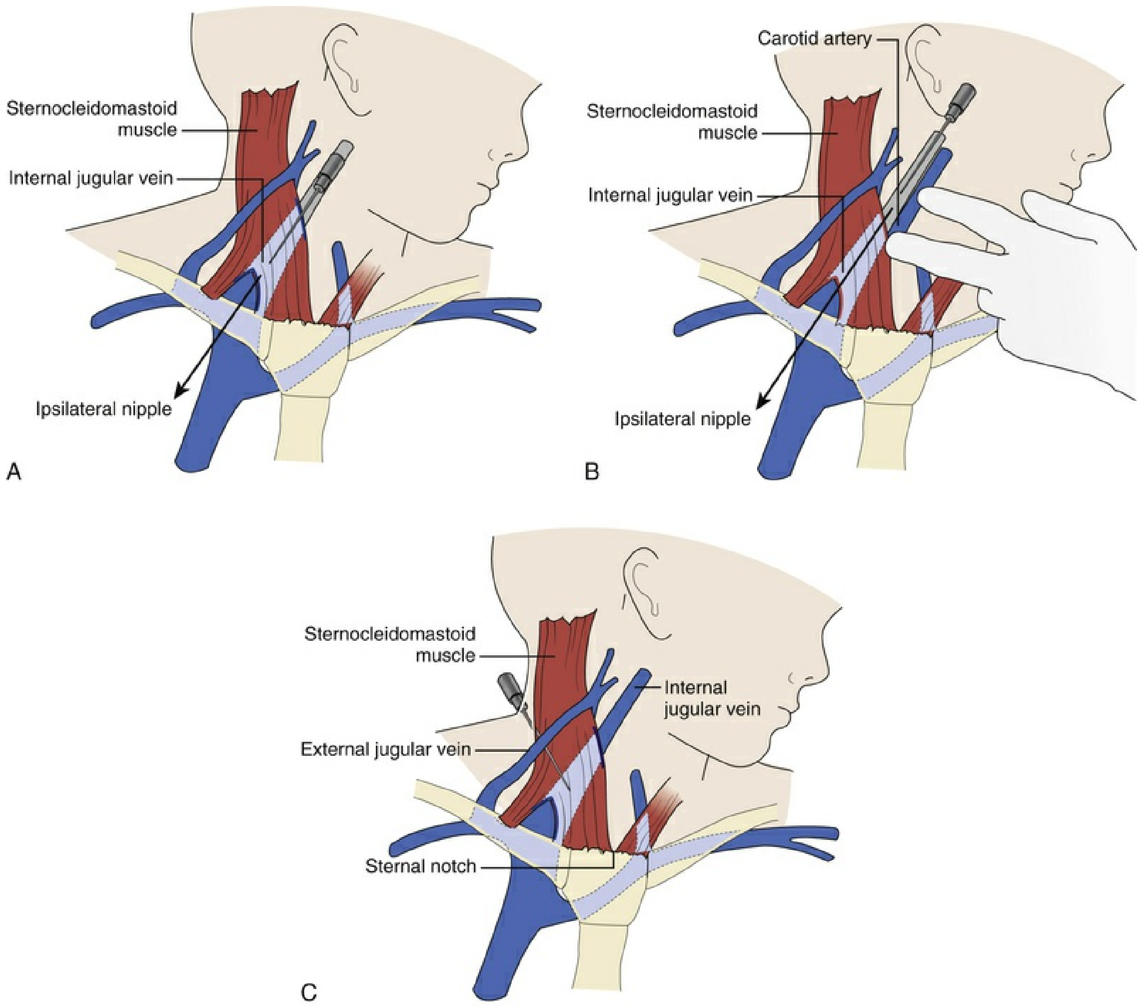

FIG. 19.7 Approaches to the internal jugular vein. The patient is supine, in slight Trendelenburg position, with the neck extended over a shoulder roll and the head rotated away from the side of the approach. (A) Middle approach. The introducer needle enters at the apex of the triangle formed by the heads of the sternocleidomastoid muscle and the clavicle and is directed toward the ipsilateral nipple at an angle of approximately 30 degrees with the skin. (B) Anterior approach. The carotid pulse is palpated and may be slightly retracted medially. The introducer needle enters along the anterior margin of the sternocleidomastoid about halfway between the sternal notch and the mastoid process and is directed toward the ipsilateral nipple. (C) Posterior approach. The introducer needle enters at the point where the external jugular vein crosses the posterior margin of the sternocleidomastoid and is directed under its heads toward the sternal notch.

Subclavian Vein Cannulation

The patient is positioned supine in a slight Trendelenburg position. A narrow roll of bed linen is placed beneath the patient, between his or her shoulders. The introducer needle enters the skin inferior to the junction of the middle and lateral third of the clavicle and is directed toward the suprasternal notch. The needle passes slightly inferior to the clavicle and enters the subclavian vein (Fig. 19.8).[95]

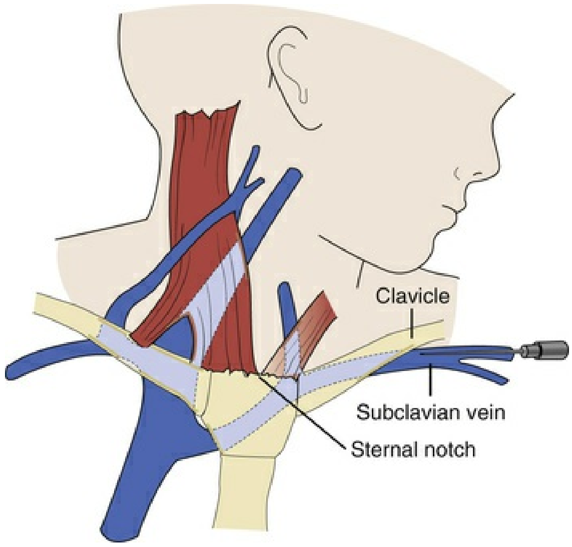

FIG. 19.8 Approach to the subclavian vein. The patient is supine, in slight Trendelenburg position, with a small roll along the spine between the shoulders. The needle enters the skin at the junction of the lateral and middle thirds of the clavicle and is directed toward the sternal notch in the horizontal plane.

Femoral Vein Cannulation

The patient is placed in a supine position either flat or in a slight reverse Trendelenburg position. A pad of bed linen is placed under the hips to slightly raise them off the bed surface. The leg on the side of catheter placement is slightly abducted and externally rotated. The femoral artery pulse is palpated just distal to the inguinal ligament about halfway between the anterior iliac crest and the pubic symphysis. The femoral vein is approximately 5 mm medial to the femoral artery in infants and toddlers and approximately 10 mm in adolescents and adults. The introducer needle enters the skin 1 to 2 cm distal to the inguinal ligament at an approximately 30-degree angle with the skin surface and in line with the course of the vein, approximately parallel to the axis of the thigh (Fig. 19.9).[95]

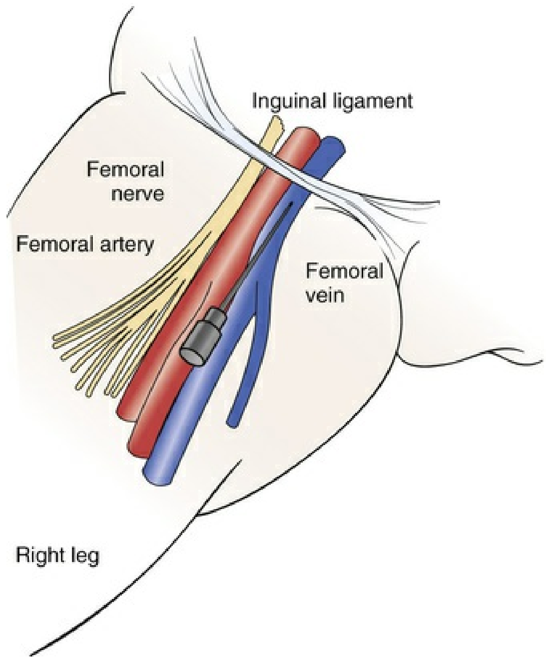

FIG. 19.9 Approach to the femoral vein. The patient is flat and supine, with the thigh slightly abducted and externally rotated. The introducer needle enters the skin 2 to 3 cm distal to the inguinal ligament and 0.5 to 1 cm medial to the pulse of the femoral artery.

Use of Ultrasound for Central Venous Line Placement

Ultrasonography is used increasingly to facilitate the placement of CVLs in the PICU. A number of studies demonstrate that the use of ultrasound reduces insertion-related complications in pediatric patients.[96-99] CVL placement success rates are improved with the use of ultrasound.[100] As familiarity with real-time ultrasound guidance is improving, novel techniques, including subclavian access, are successfully being implemented in pediatric patients.[101] Routine use of real-time ultrasound guidance for CVL placement is recommended (see also Chapter 20).

Complications

Catheter-related bloodstream infection is the most common complication (see also Chapters 11 and 110). In children, the insertion site is not related to infection risk.[102] The risk of infection is decreased by use of a bundle of practices during insertion and ongoing maintenance of the CVL. The insertion bundle includes strict full barrier precautions and sterile technique. Dressing changes with chlorhexidine skin prep, minimizing entry into the catheter, and daily assessment of the need of the catheter are all recommended during the maintenance of the catheter.[103] Currently available antibiotic impregnated catheters may decrease the risk of catheter-related infection.[104]

Pneumothorax may result if the lung is punctured during internal jugular or subclavian placement. This complication is less likely with careful patient positioning, attention to anatomic landmarks, and real-time use of ultrasonography as the introducer needle is advanced. Chest radiography should be performed after an internal jugular or subclavian catheter is attempted to document absence of

pneumothorax. Thrombosis may occur in the vessel surrounding the catheter and is associated with malignancies and diabetic ketoacidosis.[105,106]

Bleeding at the time of placement can be serious and potentially life threatening. Bleeding at the skin puncture site from an inadvertent arterial puncture is easily controlled by direct pressure. However, bleeding caused by injury to a deeper vascular structure may result in difficult-to-control hemorrhage. Veins and arteries may be perforated or lacerated distant from the intended puncture site by the introducer needle, guidewire, vessel dilator, or the catheter itself. Injury to the femoral or iliac vessels may result in pelvic or retroperitoneal bleeding. Lacerations of the internal jugular, subclavian, or innominate veins or the superior vena cava may communicate with the thoracic cavity and result in hemothorax. Bleeding complications are more severe in the presence of a coagulopathy or thrombocytopenia, and these should be treated, if possible, before central access is attempted.[107,108]

A central venous catheter positioned such that it applies pressure to the wall of the vessel or to the wall of the heart increases the risk of perforation. This situation may result in acute blood loss or tamponade. Undesirable positioning of a CVL can be detected radiographically and should be corrected as soon as possible.[107,108]

Venous Cutdown

With the widespread use of central venous access and the use of intraosseous access during emergencies, venous cutdown is rarely performed. Venous cutdown is indicated when percutaneous access is not achievable and the need for IV access warrants the more invasive procedure. Materials needed depend on the technique of vein cannulation used. The skin should be prepped and draped, and sterile technique should be used. A skin incision is made perpendicular with respect to the vein. The tissue surrounding the vein is bluntly dissected to completely expose the vein. Ligatures are passed around the vein distal and proximal to the intended site of cannulation. A small venotomy is created and, using the ligatures to control the vein, a catheter is directly passed into the lumen of the vein. The distal ligature can be tightened to control bleeding and the proximal ligature to help secure the catheter (Fig. 19.10). Alternatively, an over-the-needle IV catheter can be directly introduced into the exposed vein without creating the venotomy or using ligatures. An introducer needle and then a guidewire can be inserted into the lumen of the vein using Seldinger technique placement. The latter approach is particularly useful for femoral venous cutdown. After the catheter is in place, it is secured with suture material and the wound is closed around the catheter.

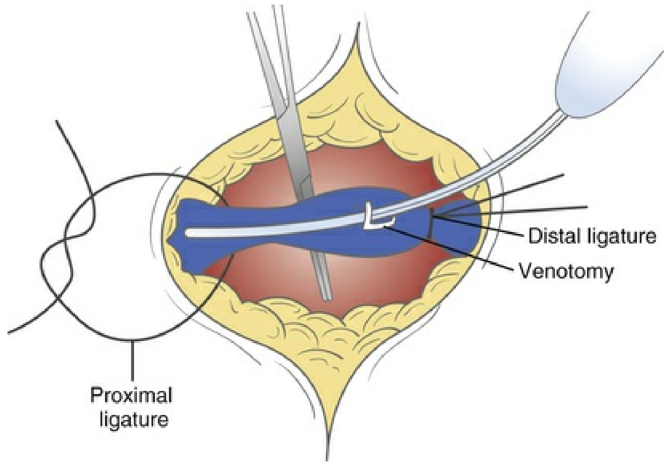

FIG. 19.10 Venous cutdown.

The complications of venous cutdown are similar to the complications of other venous access techniques. The risk of bleeding from the open wound should be considered, especially in patients with increased risk for bleeding (anticoagulation or other coagulopathy). The open wound also increases the risk of infection. Injury to adjacent structures, such as arteries and nerves, during incision and blunt dissection is a risk with cutdown.[95,109,110]

Peripherally Inserted Central Venous Catheters

PICCs are frequently used in PICU patients. For infants and smaller children, often only a single-lumen catheter can be placed. Multilumen catheters may be placed in older children. Although PICC lines can often be placed by visible location or palpation of veins in the antecubital fossae, ultrasound is frequently used to place these catheters proximal to the antecubital fossa. Success is more frequent when the catheters are inserted in the basilic vein.[111]

PICC lines are most often constructed of soft silicone or plastic polymer. The catheter length is measured prior to catheter insertion, and the catheter trimmed to the appropriate length. Placement of PICC lines is most commonly performed using a modification of the Seldinger technique. A needle or catheter is inserted into the vein, then a guidewire is placed, followed by a dilator. A soft peel-away introducer is often inserted next, with the catheter inserted through the introducer sheath; the sheath is peeled away after the catheter is in place. Outside of interventional radiology suites, chest radiography remains the primary method for documenting the location of the catheter tip.

Although PICC lines are associated with a lower risk of placement-related complications, they are subject to the same complications as percutaneous central venous catheters, including catheter-associated infection, thrombosis, perforation, embolization, and fracture.[112-115]

Pulmonary Artery Catheterization

Pulmonary artery catheter (PAC) monitoring was introduced into practice in 1970 by Swan and Ganz (see also Chapter 28). However, because of the invasiveness of the procedure and the lack of a proven survival benefit for patient management, other

less invasive surrogate techniques have significantly decreased the use of the PAC.[116-119]

Placement of the catheter can be performed at the bedside, but skill and experience in the placement, management, and data acquisition are required to avoid complications and for proper interpretation of the hemodynamic data. Most catheters are balloon tipped and flow directed, and they are able to measure right atrial, pulmonary artery, and pulmonary capillary wedge pressures as well as to determine cardiac output and oxygen saturations in the right heart chambers. Single-lumen catheters may be placed directly into the pulmonary artery at the time of cardiac surgery. Both techniques are used in pediatric patients, but the single-lumen catheter is especially used because of the frequency of pulmonary hypertension complicating the postoperative management of pediatric cardiac patients. The flow-directed, balloon-tipped catheter is usually placed in the ICU to assist in determining the etiology of shock, pulmonary edema, and pulmonary hypertension, as well as to help guide fluid and vasoactive therapy over time.

PAC should not be used for the routine care of ICU patients, but it might be recommended in heart failure patients with persistent symptoms despite standard measures and also in patients undergoing heart transplant evaluation and patients with pulmonary hypertension.[118,119] Pulmonary hypertension may either be primary or secondary, the latter including pulmonary hypertension in postoperative congenital cardiac patients. These patients are prone to wide swings in pulmonary artery (PA) pressures associated with variations in oxygenation, ventilation, and even sedation. When nitric oxide is used to manage postoperative pulmonary hypertension, direct measurement of PA pressure helps guide therapy. In patients with severe respiratory failure requiring high positive airway pressure with associated hemodynamic compromise, PACs may aid in the diagnosis of the cause of low cardiac output and direct therapy. When oxygen delivery in these patients is significantly limited because of hypoxemia, low cardiac output, or both, measurement of oxygen delivery using variables derived from information provided by the catheter may be useful. In children with severe shock unresponsive to fluid resuscitation and requiring vasoactive infusions, the PAC may better define the hemodynamic profile, thus allowing more specific therapy.

Significant controversy exists regarding the benefits and potential harms caused by this invasive form of hemodynamic monitoring.[118-120] An older multicenter observational study reported increased mortality with PACs, and subsequently several randomized clinical trials failed to demonstrate a benefit to PAC-guided therapy. Some studies showed an association with increased morbidity and mortality,[117] whereas others did not find differences with or without PACs.[120] No studies in pediatric patients have demonstrated better outcomes with the use of the PAC.

Multiple barriers exist to PAC use, including patient risk with placement, the ability to measure similar variables via less invasive measures, increased cost, inaccurate measurement leading to misuse of PAC-derived variables, and incorrect interpretation and clinical application. Additionally, with the decreased use of this technology, the skill required to maintain competency in placement and interpretation of the data provided presents a significant challenge to many institutions.

Contraindications

There are no specific contraindications to placement of a PAC, but there are several relative contraindications, including bleeding diathesis increasing the risk for percutaneous access, as well as severe tricuspid or pulmonary insufficiency, which can make bedside catheter placement prohibitively difficult. Unstable cardiac arrhythmias that are easily triggered by catheter manipulation are also a relative contraindication. Catheter placement for measurement of cardiac output using the thermodilution technique is contraindicated in the presence of intracardiac shunts, tricuspid insufficiency, or pulmonary insufficiency, as the thermodilution measurement will be inaccurate.

Procedure and Equipment

Choosing the most appropriate size and type of catheter is often difficult because a variety of balloon-tipped, flow-directed catheters are available on the market. Catheters are available with two diameters, 5 Fr and 7 Fr. The 5-Fr diameter catheter is most appropriate for patients weighing less than 15 kg, and the 7-Fr diameter catheter is best for patients weighing more than 15 kg. Some PACs employ fiberoptic spectrophotometry for continuous measurement of mixed venous oxygen saturation. Single-lumen PACs are most commonly placed in the operating room at the time of heart surgery.

The standard PAC is 1 m long. The PAC is equipped with proximal and distal ports facilitating measurement of intravascular pressures, infusion of vasoactive agents, fluids, and blood sampling. The distance between the proximal and distal lumen ports varies depending on the catheter: Standards are 10, 15, 20, and 30 cm. Using the correct distance is crucial in order to monitor the appropriate pressure. At the tip are a thermistor used to calculate cardiac output and a balloon that may be inflated and deflated as necessary. Some catheters have an additional right ventricular port for temporary pacemaker insertion, and some have the fiberoptic oxygen saturation sensor for continuous measurement of mixed venous oxygen saturation. Other necessary equipment includes a monitor with cardiac output capability or a computer to determine cardiac output using thermodilution, as well as compatible pressure transducers. Carbon dioxide is used in some centers to inflate the balloon so as to minimize the risk of air embolization, although room air is most common. The catheters are placed through a percutaneous introducer sheath, which is placed with the same technique as described for central venous catheters.

Before placement, the catheter should be flushed and filled with fluid through which intravascular pressures are transmitted to a transducer. The equipment is then zeroed to atmospheric pressure at the level of the patient's left atrium (midaxillary line, fourth intercostal space) and calibrated. If all air bubbles are not removed from the tubing, they may result in *damping* of the waveform tracing and, consequently, erroneously low systolic pressure. Thrombus at the tip of the catheter may also alter the waveform.

The insertion site is prepared in sterile fashion with chlorhexidine solution and draped with sterile towels. It is important to drape a wide area with sterile sheets (full field barrier drape) in order to avoid exposure of the catheter, because of the length of the PAC. The PAC is inserted through the introducer sheath. A sterile sleeve is placed on the end of the sheath, and the catheter is passed through the

sleeve, then through the introducer diaphragm and into the sheath.

Anatomically, the preferred sites of insertion are the right internal jugular, left subclavian, right subclavian, and left internal jugular veins. Usually, the placement of the catheter is guided by pressure waveform monitoring (Fig. 19.11), but fluoroscopic visualization will occasionally be needed, particularly if the PAC is placed from a femoral site. Once the catheter tip enters the venous circulation, the balloon is inflated with air. From this point, the catheter should be advanced with the balloon inflated so as to prevent damage to the myocardium, cardiac valves, or pulmonary artery branches. If the catheter is withdrawn, the balloon must first be deflated to avoid valvular injury.

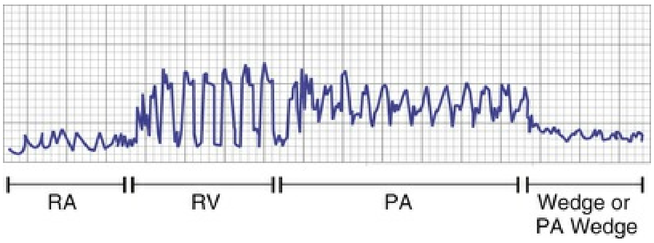

FIG. 19.11 Pressure tracing during placement of a pulmonary arterial catheter showing pressures from the right atrium (RA), right ventricle (RV), and pulmonary artery (PA), then pulmonary capillary wedge pressure. (From Adatia I, Cos P. Invasive and noninvasive monitoring. In Chang AC, ed. Pediatric Cardiac Intensive Care. Baltimore, MD: Lippincott Williams & Wilkins; 1998.)

The catheter is advanced to the right atrium (RA), then across the tricuspid valve into the right ventricle (RV), and across the pulmonary valve into the PA. As the catheter continues to float with the balloon inflated, it will wedge in a branch PA, occluding the blood flow. The pulmonary artery occlusion pressure (PAOP), or wedge pressure (PAWP), will be recorded from the distal lumen. If the balloon is deflated, a PA pressure tracing will be recorded. If the waveforms are not obtained, the balloon should be deflated and the catheter pulled back to the RA before attempting placement again.

After insertion, a chest radiograph is obtained to ensure proper catheter placement and rule out pneumothorax. The catheter tip should be visualized ideally within West zone III of the lung (see also Chapter 28).

The pressure waveforms are characteristic; when the catheter is advanced to the RA, the atrial trace has a respiratory variation that helps to confirm the catheter is in the thorax. Once in the atrium the balloon is inflated and advanced to the RV, where the trace is characterized by a rapid upstroke in early systole with an equally rapid downstroke at the end of systole and diastolic pressure near zero. Turning the catheter with a clockwise motion usually helps in passing the PAC. The catheter is advanced to the PA. The PA trace has the same peak systolic pressure of the RV, but as systole ends, the trace shows a slower fall that continues through diastole, because the diastolic pressure in the PA is higher than the RV diastolic pressure. Once in the PA, the catheter is advanced slightly until a pulmonary wedge trace is seen. This trace is similar to the RA trace, although usually with a higher pressure. PAWP is obtained when the balloon is inflated and the catheter floats into the wedge position (see Fig. 19.11). Because the catheter floats to an area of greatest blood flow in the

lung, it most likely will be in an area consistent with West zone III, where arterial pressure is higher than both venous and alveolar pressures.

Measurement of PAWP is best done at end-expiration to minimize the effect of changes in pleural pressure. Once the wedge is measured and the balloon is deflated, the PA trace should return. If the trace does not change, the catheter should be retracted until the PA trace is seen. The catheter should not be left inflated in the wedge position because of the risk of pulmonary infarction. The catheter is appropriately positioned when the PA pressure trace is present when the balloon is not inflated and the pulmonary capillary wedge trace is present when the balloon is inflated. Once it has been confirmed that the PAC is in good position by pressure trace and radiography, the catheter should be secured in the sleeve and taped to the patient.

Information Acquisition

Much hemodynamic and oxygen delivery information can be obtained from the Swan-Ganz–type PAC. Multiple hemodynamic pressures can be obtained, including RA, RV PA, and PA wedge pressures. Right atrial pressure is useful for determining preload of the right ventricle. Pulmonary artery pressure is useful for determining the presence of pulmonary hypertension both at baseline and with manipulation of oxygenation, ventilation, ventilator pressures, nitric oxide, and other procedures. PAWP reflects left ventricular preload. In most patients with normal cardiac function and anatomy, right atrial or central venous pressure adequately reflects LV preload as well. However, in the presence of certain congenital heart defects, with significant ventricular dysfunction, or with high mechanical ventilatory pressures, a significant discrepancy may exist between right and left ventricular preload. In such circumstances, measurement of PAWP may be useful for guiding fluid and inotropic therapy.

Mixed venous oxygen saturation ($S_{mv}O_2$) can be determined directly and continuously with a catheter containing the fiberoptic oximeter. In the absence of the oximeter, intermittent blood sampling from the distal port when in place in the pulmonary artery allows for $S_{mv}O_2$ measurement.

The thermistor at the tip of the catheter allows for measurement of cardiac output, using the thermodilution method. This method uses the Fick principle, based on the law of conservation of thermal energy. A specific amount of known temperature fluid is injected in the proximal port (upstream), and the temperature change downstream (at the thermistor) is recorded. The change in temperature over time allows for measurement of blood flow, in this case cardiac output. According to Jansen, this measure of cardiac output is accurate if the following conditions are met: (1) no loss of cold occurs between the injection site and the thermistor, (2) mixing of the cold injectate (indicator using Fick terms) and the blood is complete, and (3) the temperature change caused by the injection of cold fluid is sufficient to be detected by the thermistor.

To perform thermodilution cardiac output measurements, the catheter must be connected to the thermodilution computer, which is either freestanding or part of the cardiac monitor. A specific volume of injectate, either room temperature or iced, is injected rapidly into the proximal port of the catheter. The temperature difference over time that is detected at the thermistor is recorded as a curve. The computer then

integrates the area under the curve, which is inversely proportional to the cardiac output. The cardiac output is calculated and projected. For pediatric patients, this number should be divided by their body surface area in square meters, deriving the cardiac index. The injectate can be either iced or room temperature. The disadvantages to iced injectate include risk of hypothermia in pediatric patients requiring frequent cardiac output measurements, the poor accuracy of the first injection because of warmer fluid in the catheter, and a greater signal-to-noise ratio. Room-temperature injectate prevents these problems and yet is accurate when cardiac output is stable. However, in conditions of high or low cardiac output, less variance occurs with iced injectate compared with room-temperature injectate. However, for convenience and the safety of pediatric patients, room-temperature injectate is recommended.

Usually three to five injections yield adequate results. Some error can be introduced by faulty technique. Injecting variable volumes or injecting with variable rates can result in inaccurate measures. Multiple injections and averaging of the results can overcome these problems. The presence of tricuspid or pulmonary insufficiency can lead to an overestimation of cardiac output. Echocardiography may be necessary to rule out the presence of valvular insufficiency. Intracardiac shunts, such as a ventricular septal defect, result in false values for cardiac output. Mechanical ventilation has been shown to alter stroke volume, which can result in a variability of cardiac output measurements. Therefore one should perform the injection at the same time in the ventilator cycle to standardize the cardiac output measurements.

Maintenance

Care of the PAC is similar to that for any central venous line. The catheter and sheath should be dressed sterilely at all times and the dressing changed according to protocol. The catheter is housed in a sterile sleeve that allows for aseptic technique if further manipulation is necessary. Pressure transduction of the distal (PA) and proximal (RA) ports and continuous ECG monitoring are mandatory. This setup continually confirms proper placement of the catheter. Whenever the balloon is inflated to determine PAWP, the balloon is allowed to deflate passively by opening the balloon port and removing the syringe. This step helps prevent balloon rupture. Balloon rupture should be suspected if blood is obtained when aspirating the balloon port. In this situation, remove and then replace the catheter if it is still clinically indicated. As noted earlier, arrhythmias can occur, particularly if the catheter becomes dislodged. A chest radiogram should be assessed daily for catheter position.

Interpretation

The hemodynamic data obtained or calculated with the PAC should be interpreted to make therapeutic decisions. There are not isolated "good" or "bad" cardiac output (CO) values, but appropriate cardiac output is that which permits an adequate oxygen delivery (DO_2). As a global index of adequacy between consumption (VO_2) and DO_2, $S_{mv}O_2$ is the target of choice for therapeutic decisions. $S_{mv}O_2$ should be kept above a threshold value between 65% and 70%, and all other PAC parameters

should be used to choose how to maintain $S_{mv}O_2$ above this value. This $S_{mv}O_2$ goal can be achieved by fluid administration, blood transfusion, increasing or decreasing inotropic support, or vasopressors.[116,121]

Complications

PA catheterization is a significantly invasive procedure. Complications can occur during the Seldinger procedure to access the vein, during the passage of the PAC (across two heart valves), or during catheter use. Bleeding, infection, and pneumothorax may occur during venous access. Arrhythmias can be seen during placement of the PAC or due to dislodgment of the catheter. Their spectrum includes supraventricular tachycardia while the PAC tip is in the RA to premature ventricular beats or even ventricular tachycardia while the PAC tip is in the RV. Usually, the arrhythmias cease when the catheter tip reaches the pulmonary artery. Occasionally lidocaine, amiodarone, and defibrillation may be needed, so they should be readily available. Once the catheter is in place, pulmonary infarction or hemorrhage is a risk. Rupture of the distal pulmonary artery, endothelial damage, and valvular damage have been reported, as well as knotting of the catheter requiring fluoroscopic retrieval. The PAC should be removed as soon as possible to minimize the risk of complications.

Summary

Since the introduction of the PAC, controversy has surrounded the technology regarding the benefits and potential harms caused by this invasive form of hemodynamic monitoring. In adult clinical trials, the usefulness of the PAC has been challenged because no benefit in patient outcome has been observed, and some retrospective studies have described worse outcomes. Accurate acquisition and interpretation of PAC data are paramount for making appropriate therapeutic decisions.

Thoracentesis and Tube Thoracostomy

Thoracentesis

Thoracentesis is a procedure to remove fluid or air from the pleural space. In pediatric patients, thoracentesis is most frequently used as a diagnostic procedure. Pleural effusions in children are most commonly the result of an infectious process (50% to 70% parapneumonic effusions), with congestive heart failure (5% to 15%) and malignancy being less common causes.[122] Many other conditions may, rarely, cause pleural effusions in children (Box 19.2).

Box 19.2

Causes of Pleural Effusion

Infection (exudates)

- Bacterial
- Viral
- Fungal
- Mycobacterial
- Mycoplasma

Cardiovascular

- Congestive heart failure
- Constrictive pericarditis
- Superior vena cava obstruction

Pulmonary

- Pulmonary infarction
- Atelectasis
- Asbestos exposure
- Drug-induced pleuritis

Intraabdominal disease

- Abdominal surgery
- Pancreatitis
- Hepatitis
- Peritonitis
- Subdiaphragmatic abscess
- Intrahepatic abscess

- Meigs syndrome
- Cirrhosis with ascites

Iatrogenic

- Extravascular central venous catheter placement

Collagen vascular disease

- Rheumatoid arthritis
- Systemic lupus erythematosus
- Sjögren syndrome
- Wegener granulomatosis

Neoplastic

- Lymphoma/leukemia
- Mesothelioma
- Chest wall tumors
- Metastatic carcinoma
- Bronchogenic carcinoma

Renal

- Uremia
- Urinary tract obstruction
- Nephrotic syndrome
- Peritoneal dialysis

Miscellaneous

- Esophageal rupture

- Hemothorax
- Chylothorax
- Lymphedema
- Hypoalbuminemia
- Myxedema
- Sarcoidosis
- Radiation therapy
- Immunoblastic lymphadenopathy
- Familial Mediterranean fever

Indications

Thoracentesis may be used diagnostically or therapeutically to relieve respiratory distress resulting from large accumulations of fluid or air. If ongoing evacuation is required, tube thoracostomy should be considered (discussed later). Ultrasound is useful to identify fluid accumulations when there is complete opacification of the hemithorax on chest radiograph and to help characterize fluid consistency (complicated versus simple effusions). Ultrasound may also help to identify optimal locations for successful aspiration.[123]

Contraindications

Thoracentesis has no absolute contraindications. Positive pressure ventilation may increase the risk of pneumothorax. Uncorrected coagulopathy and thrombocytopenia predispose to bleeding complications; however, thoracentesis can generally be accomplished in this setting utilizing a small needle and careful technique. An uncooperative patient can lead to damage to the underlying vascular structures and lung parenchyma. This can be avoided by generous use of sedation and analgesia.

Preparation

Sedation and analgesia are frequently required to safely perform thoracentesis in pediatric patients. Topical local anesthetic agents may reduce the discomfort associated with infiltration of local anesthetics and should be placed at the insertion site at least 15 to 30 minutes prior to the procedure (depending on agent).

Procedure

Box 19.3 lists the supplies and equipment required for thoracentesis.

Box 19.3

Supplies and Equipment for Thoracentesis

- Pillows or towels for positioning patient
- Sterile gloves
- Povidone-iodine or chlorhexidine solution
- Commercial thoracentesis tray (for older children and adolescents)
- Or assemble the following items:
- Sterile gauze sponges
- Sterile towels or drapes
- 3- to 5-mL syringe for local anesthetic; 27- to 30-gauge needle for skin infiltration
- 1% lidocaine; consider sodium bicarbonate to buffer lidocaine
- Over-the-needle catheter: 14- to 20-gauge depending on the size of the patient
- 10- or 20-mL syringes for fluid collection
- Three-way stopcock or tubing extension set with clamp
- Sterile dressing
- Tape to secure dressing

Technique

If thoracentesis is being performed for evacuation of a pneumothorax, the patient should be placed in the supine position. Aspiration is performed at the second or third intercostal space in the midclavicular line. For removal of pleural fluid, the patient should be placed in the upright, seated position. Infants and young children may be held in the burping position by an assistant. The normal site for fluid aspiration is the seventh intercostal space in the posterior axillary line (near the tip of the scapula).

The site should be prepped with chlorhexidine and draped with sterile towels. The skin entry site is then generously infiltrated with a local anesthetic using a 27- to 30-gauge needle. The needle is then advanced perpendicular to the skin to infiltrate the

underlying subcutaneous tissues, superior portion of the rib, and periosteum. A longer 22- to 25-gauge needle may be needed to accomplish this goal. The needle is then advanced over the superior border of the rib while gentle pressure is applied on the syringe plunger until the pleural space is reached. The depth of the needle where fluid aspiration occurs should be noted. An over-the-needle catheter of sufficient length is then used for aspiration of fluid with a syringe. If infection and exudate effusion are suspected, a larger catheter (16- to 18-gauge) may be needed.

Aspiration is continued until a sufficient quantity of fluid for diagnostic studies is obtained. A three-way stopcock with attached tubing may be placed on the catheter to facilitate this process. If fluid is being removed for the release of respiratory distress, aspiration is continued until fluid flow ceases. The catheter is subsequently removed and a sterile dressing is applied over the entry site.

Complications

The most common complication of thoracentesis is pneumothorax.[123] All patients undergoing thoracentesis should have a follow-up chest radiograph. Hemothorax may occur in patients with abnormal coagulation or thrombocytopenia. A platelet count of greater than 50,000/uL and normal coagulation studies are ideal, but the procedure can be safely performed with careful technique and avoidance of the neurovascular bundle found on the inferior border of the rib. In more urgent settings, platelets and clotting factors may be administered during the procedure. Soft tissue infections can be avoided with use of proper sterile technique. Reexpansion pulmonary edema has been reported in adult patients with removal of large fluid volumes and usually occurs in the first hour following thoracentesis.[124,125] This complication has not been reported in children.

Interpretation

Analysis of pleural fluid is separated into two basic categories: exudates and transudates. The criteria used to distinguish between the two are largely dependent on adult data.[126] Box 19.4 lists the Light criteria for differentiating between transudative versus exudative fluid. Elevated triglyceride levels (greater than 110% of serum value) and lymphocyte predominance suggest chylothorax. Elevated amylase suggests pancreatitis or esophageal rupture.[127] Advances in polymerase chain reaction (PCR) technology allow for rapid and accurate diagnosis of *Staphylococcus aureus, Streptococcus pneumoniae,* and *Mycoplasma* in pleural fluid.[128]

Box 19.4

Interpretation of Pleural Fluid

Characteristics of exudative effusions:

- Pleural to serum protein ratio >0.5
- Pleural to serum lactate dehydrogenase (LDH) ratio >0.6

- Pleural fluid LDH more than twice the upper limit of the normal serum value

Summary

Thoracentesis is a useful diagnostic procedure for pediatric pleural effusions. It can also be a useful technique resolving respiratory distress with significant fluid accumulations or pneumothoraces. Thoracentesis is a simple technique that can be performed with high yield and a minimal complication rate.

Tube Thoracostomy

Tube thoracostomy placement is a common procedure in the pediatric critical care setting. Many options, including less invasive techniques, are now available and are discussed here. Tube thoracostomy is required for a variety of reasons in critically ill pediatric patients. Pneumothoraces can develop spontaneously or as a result of acute lung injury. Large parapneumonic effusions and empyemas resulting from infectious pulmonary processes often require chest tube placement. Hemothoraces or hemopneumothoraces resulting from trauma frequently require drainage. Finally, chylothoraces in postoperative cardiac patients frequently require tube placement and continuous drainage. The technique utilized for placement depends on the nature (thick, thin, transudative, exudative) of the material to be removed.

Contraindications

As with thoracentesis, tube thoracostomy has no absolute contraindications. Attempts should be made to correct coagulopathy to prevent bleeding complications. However, when emergent or urgent intervention is required, tube thoracostomy should not be delayed.

Supplies and Equipment

Many institutions have specially designed chest tube trays with sterile instruments. Typical requirements include sterile gauze sponges, sterile towels for draping, syringes and needles for local anesthesia, a scalpel and blade, curved Kelly clamps of various sizes, needle driver, suture, and suture scissors. Other materials required are an appropriately sized chest tube, chlorhexidine solution, sterile gloves, a drainage apparatus (such as Pleur-Evac), local anesthetic, and tape.

Technique

Patients should receive sedation and analgesia for tube thoracostomy, along with generous local anesthesia. The technique for placement depends on the type of material expected to be removed from the chest. Thin, transudative fluid and pneumothoraces can often be evacuated with placement of a small-caliber tube (5 Fr to 9 Fr) via a modified Seldinger technique.[129]

After proper sedation and analgesia, the overlying skin is prepped with chlorhexidine and draped in sterile fashion. A needle attached to a syringe (5 or 10 mL) is inserted in the fourth or fifth intercostal space in the midaxillary line. Continuous suction is applied and the needle is advanced until fluid or air is

obtained. A guidewire is then placed into the pleural space. A small skin incision is made and the overlying skin and subcutaneous tissues are dilated with a skin dilator. A small catheter with multiple side holes is then placed over the wire and advanced into the pleural space. The guidewire is removed and the catheter is attached to a standard chest tube suction device. The tube is anchored to the skin with a suture or a commercially available sutureless skin-anchoring device. Placement of pigtail catheters tends to be less painful than traditional tube thoracostomy (described later); however, the viscous fluids encountered with hemothoraces and empyemas generally do not drain well via this technique. Successful treatment of empyema with placement of pigtail catheters and use of fibrinolytic agents (alteplase and streptokinase) has been described.[130]

A variation of this technique allows for placement of larger caliber tubes. After placement of the guidewire as above, progressive skin dilators are used, allowing placement of a more standard-sized chest tube. Kits for placement of these over-the-wire devices are commercially available. Caution should be used with placement of these devices in diseases with poor pulmonary compliance or pulmonary hyperinflation, as these conditions may predispose to intraparenchymal tube placement and the development of bronchopleural fistulas.[131]

Traditional techniques for tube thoracostomy may be required for drainage of viscous fluids, including cases of empyema and hemothorax. Tube thoracostomy is a painful procedure and requires generous use of sedation and analgesia. Following administration of sedation and analgesia, the patient is placed in the supine position. The skin is prepped with chlorhexidine and draped in sterile fashion. The proper position for placement is the fourth or fifth intercostal space in the midaxillary line. The skin, subcutaneous tissues, intercostal muscles, underlying rib, and periosteum should be generously infiltrated with local anesthetic as described above.

A skin incision in the fourth or fifth intercostal space, large enough to allow placement of the chosen tube, is made parallel to the axis of the rib in the midaxillary line. A curved Kelly clamp is used to bluntly dissect the underlying subcutaneous tissue until the superior border of the upper rib is reached. The clamp is then used to push through and dilate the intercostal muscle and pleura insertion above the superior border of the rib. In a larger child, the index finger can be used to further dilate the subcutaneous tissues and intercostal muscles. Any intrapleural adhesions can also be manually broken up. The end of the tube is then attached to a clamp and inserted into the pleural space. The clamp is opened and the tube advanced to the proper depth, ensuring all side holes are in the chest cavity. If possible, the tube should be advanced anteriorly for pneumothoraces and posteriorly for effusions. The tube is then attached to a pleural drainage system.

Many techniques are available for suturing the chest tube in place. The most important aspect of the choice of anchoring method is that the operator removing the tube knows how the tube was secured. Some operators prefer a horizontal mattress suture on both sides of the tube; others prefer to place a *pursestring suture* that can be pulled together after the tube is removed. If the latter technique is used, no knot is placed at the skin level, but extra suture is wrapped around the body of the tube and then tied to the tube itself. Upon removal, the extra suture serves as skin suture for the wound. Rarely, a suture is inadvertently placed through the tube while the device is anchored. In this event, a technique for cutting the suture using endoscopic scissors has been described.[132] Needleless anchoring devices for anchoring tubes

without suture (eg, StatLock Multipurpose, Venetec International, San Diego, California) are commercially available.

Maintenance

Following successful chest tube placement, a chest radiograph should be obtained to verify proper position and to evaluate for resolution of pleural fluid or pneumothorax. Tubes should be evaluated for continued air leak by checking for air bubbles in the leak chamber of the suction apparatus. Persistent air leak with no evidence of pneumothorax by chest radiograph suggests the development of a bronchopleural fistula or airway injury. Some authorities suggest intermittent external negative pressure to "strip" the tube in order to maintain patency, although little evidence supports this practice.[133] Alteplase may also restore patency of tubes clogged by proteinaceous material.[130] Some advocate prophylactic antibiotic use, but little evidence supports this practice.[134]

Timing of tube removal depends on the indication for placement. Tubes placed for pneumothoraces may be removed following resolution of the air leak. The authors' practice is to place these tubes to water seal for at least several hours and obtain a chest radiograph prior to removal. This practice of placing tubes to water seal and evaluating with a chest radiograph is supported in the adult literature.[135] Tubes placed for drainage of pleural fluid may be safely removed once fluid drainage has decreased to 2 to 3 mL/kg/24 hours. Removal of large tubes may be painful and require analgesia or sedation, especially in small children. Tubes may be safely removed during either the inspiratory or expiratory phase.[136]

Complications

Several potential complications exist with placement of chest tubes. Any structure within the thorax may be inadvertently penetrated with use of undue force. For this reason, trocar chest tubes are not recommended for use in children, even in emergent situations. Placement in the lung parenchyma is relatively common, potentially leading to bronchopleural fistulas.[137] Vascular injury may occur with high placement, and subclavian artery obstruction has been reported as well.[138] Left-sided placement can lead to thoracic duct injury and development of chylothorax. Deep placement may lead to mediastinal perforation.[139] Computed tomography may be used to evaluate the exact placement of chest tubes in cases where inadvertent misplacement or complications are suspected.

Summary

Tube thoracostomy is a common procedure in pediatric critical care. With attention to detail, this procedure may be accomplished safely and with minimal risk. New techniques and smaller caliber tubes may be utilized in select cases. Fibrinolytic agents such as alteplase may be used to restore the patency of clogged tubes and may be of therapeutic benefit in cases of empyema.

Paracentesis

Paracentesis is the percutaneous sampling of peritoneal fluid by needle aspiration through the abdominal wall and is considered a relatively safe procedure. Analysis

of ascitic fluid, combined with history and physical examination, will frequently confirm the cause of ascites.

Indications

Diagnostic paracentesis is indicated in any patient with new-onset ascites, when the cause of ascites is unknown, or cases of suspected bacterial peritonitis.[140,141] Paracentesis may also be used for the relief of respiratory distress or the end-organ effects of abdominal compartment syndrome secondary to massive ascites.[142]

Contraindications

Paracentesis in patients with ascites has no absolute contraindications, except when overt disseminated intravascular coagulation is present.[140,141,143,144] Severe renal dysfunction has the highest association with bleeding complications after paracentesis.[140,141,145] Due to the very low risk of bleeding complications and lack of data to support their use, the routine use of prophylactic fresh frozen plasma or platelets is not currently recommended.[140,141]

Procedure

When present, the physical examination findings of flank dullness, shifting dullness, and fluid waves support the presence of ascites and can guide selection of the needle insertion site.[140,141,143] Ultrasound guidance may improve the success rate of paracentesis.[146,147] Additionally, when physical exam findings are insufficient or difficult due to obesity, ultrasonography can detect smaller amounts of fluid, differentiate free from loculated fluid, and may be more sensitive than physical examination in diagnosing ascites.[140,141,148]

Supplies

Box 19.5 lists the supplies required for diagnostic paracentesis.

Box 19.5

Supplies for Diagnostic Paracentesis

- Antiseptic solution
- Alcohol preps
- Sterile gauze
- Sterile drapes
- Sterile gloves
- 1% lidocaine with or without epinephrine
- 3- to 10-mL syringe with small-gauge needle for local anesthesia

- 22- to 16-gauge spinal needle or intravenous catheter (22- to 20-gauge needle for small children, 16- to 20-gauge needle for larger children)
- 20-mL (or larger) syringe
- Specimen vials

Technique

The patient is positioned in semirecumbent position. The bladder should be emptied by voiding or catheterization. The site of needle insertion is selected by physical examination or ultrasound. Outside of the neonatal period, preferred sites are midline along the avascular linea alba below both the umbilicus and the upper edge of dullness but above the bladder (usually midpoint between umbilicus and pubic symphysis suffices) or the left lower quadrant two finger breadths (2–3 cm) in both the medial and cephalad directions from the anterior superior iliac spine. The right lower quadrant may also be used. Surgical scars should be avoided due to the risk of underlying bowel adhesions.[140,141,143] The inferior epigastric arteries running cephalad midway between the pubic symphysis and anterior iliac spine in the rectus sheath should be avoided. In patients with portal hypertension, the midline may become vascularized and should be avoided, as well as any visible collateral vessels, to reduce the chance of hemorrhagic complications.[140,141,143,149]

The entry site is disinfected with antiseptic solution, such as chlorhexidine or povidone iodine, and draped in sterile fashion. The skin and subcutaneous tissue down to the peritoneum are infiltrated with lidocaine using a small-gauge needle. Prior to needle insertion, the skin at the insertion site should be pulled downward approximately 2 cm, to create a nonlinear Z tract, and while holding negative pressure with the attached syringe, the clinician inserts the needle. The needle is advanced slowly until free flow of fluid into the syringe is noted, but it is removed immediately if frank blood is aspirated. If an IV catheter is utilized, the catheter should be advanced and needle removed at this time, with reattachment of the syringe to the catheter. Approximately 20 to 40 mL of fluid is collected for diagnostic evaluation, but much larger volumes, 1 to 5 liters depending on age, may be removed for tense ascites.[140-143] If fluid return stops or is sluggish, changing the patient's position may be helpful. Once fluid collection is complete, the needle or catheter is removed, direct pressure with gauze is applied, and then a sterile pressure dressing placed. When ongoing drainage is needed, a pigtail catheter can be placed using the Seldinger technique.

Complications

Potential complications of paracentesis occur in approximately 1%, most commonly abdominal wall hematoma or bleeding.[143] Additional, but rare (<0.1%), complications include persistent leakage of ascitic fluid, bladder perforation, intestinal perforation with and without resulting peritonitis, and scrotal edema.[141,143,150,151] In patients with bleeding complications, renal dysfunction was present in 70%, coagulopathy 59%, and thrombocytopenia 8%.[145] Appropriate selection of the needle insertion site minimizes the risk of hematoma or bleeding. The risk of intestinal perforation is increased in patients with previous abdominal surgical procedures with adhesions

and can be minimized by avoiding abdominal surgical scars at the needle insertion site.[140,141,152,153] Additionally, intestinal perforation has been reported with marked bowel distension, and, though rare, decompression should be considered prior to paracentesis.[151] Persistent leakage of ascitic fluid can be minimized by using the Z-tract method for needle insertion and a smaller bore needle. Ongoing fluid leaks can be managed by closing the defect with a suture or applying cyanoacrylate skin adhesive.[154] Bladder emptying decreases the risk of bladder perforation. Strict adherence to sterile technique and avoidance of areas of skin or soft tissue infection decrease the risk of infection.

Interpretation

Analysis of ascitic fluid may not yield a definitive diagnosis, but it is useful in the evaluation of ascites. Clinical assessment identifies the most likely diagnosis, helps determine which tests should be ordered, and influences the interpretation of results.[140,141,155,156]

Fluid studies that should be obtained include total protein, albumin, and white blood cell count with differential. Optional studies to consider are Gram stain, aerobic and anaerobic cultures (inoculated into culture bottles at the bedside), glucose, lactate dehydrogenase, and amylase. Rarely needed studies to consider are acid-fast bacilli (AFB) smear and culture, cytology, triglyceride, and bilirubin. Studies considered unhelpful are pH, lactate, cholesterol, fibronectin, and glycosamioglycans.[140,141] Corresponding serum chemistries should be obtained for comparison.

Analysis of the serum-ascites albumin gradient (SAAG) is useful for differentiating between ascites caused by portal hypertension and ascites resulting from other causes. A SAAG of 1.1 g/dL or higher correlates with portal hypertension with 97% accuracy.[141,155]

The characteristics of ascitic fluid in various conditions are summarized in Table 19.2.

TABLE 19.2

Characteristics of Ascitic Fluid in Various Conditions

Condition	Clinical Characteristics	Laboratory Findings
Portal hypertension	Straw colored, sterile	SAAG ≥1.1 g/dL Total protein <2.5-3 g/dL WBC <250-500/uL, <1/3 neutrophils
Spontaneous bacterial peritonitis	Cloudy or turbid Gram stain positive <10%, cultures may be negative, single organism[a]	Neutrophils ≥250/uL Total protein <1 g/dL LDH and glucose similar to serum
Secondary bacterial peritonitis	Multiple organisms	Neutrophils ≥250/uL Total protein >1 g/dL LDH elevated Glucose <50 mg/dL
Chylous ascites	Milky with recent fat ingestion	WBC 1000-5000/uL, predominately lymphocytes Triglycerides >200 mg/dL, cholesterol >48 mg/dL[b]
Pancreatic ascites	Turbid, brown or bloody	WBC and total protein increased Amylase and lipase levels >serum Amylase levels may be falsely low in young infants[c]
Urinary ascites		Protein <1 g/dL; urea and creatinine >serum[d]

Malignant ascites	Bloody	Protein and LDH elevated
Nephrotic syndrome	Straw colored	Total protein <2.5 g/dL[c]
Tuberculous ascites	Yellow or bloody, may have fibrin clots	Total protein >2.5 g/dL WBC >1000/uL, primarily lymphocytes PCR useful[¶]

LDH, lactate dehydrogenase; *PCR*, polymerase chain reaction; *SAAG*, serum-ascites albumin gradient; *WBC*, white blood cells.

Summary

Needle aspiration of ascitic fluid is a relatively safe procedure when performed with appropriate precautionary measures. Analysis of ascitic fluid obtained by paracentesis is useful in the evaluation of patients with new-onset ascites, unknown cause of ascites, or suspected bacterial peritonitis. Ongoing drainage through a catheter placed at the time of paracentesis may improve ventilation or reduce complications secondary to abdominal compartment syndrome in patients with massive ascites.

CHAPTER 20

Emerging Role of Ultrasonography in the Pediatric Intensive Care Unit

Erik Su, Akira Nishisaki, Thomas Conlon

PEARLS

- Intensivist-operated ultrasound is an important adjunct for vascular procedures at the pediatric intensive care unit bedside, and it is considered standard of care for percutaneous internal jugular vein central access. Evidence also suggests its utility in vascular access in other central vessels, peripheral veins, and arteries as well.
- Accuracy of intensivist-operated ultrasound examining the heart, lungs, abdomen, and cerebral circulation has also been explored. Cardiac ultrasound examinations by intensivists demonstrate sensitivity for pathology similar to studies performed by imaging specialists.
- Practice and familiarity with ultrasound's capabilities, advantages, and disadvantages contribute to responsible and effective practice.
- An image archival system is a core asset in the development of a program for documentation, quality improvement, education, and research purposes.

More than a technologic advancement in critical care medicine, ultrasound has been a positive innovation in the pediatric ICU, providing a means of facilitating procedure guidance and basic patient assessment. Since the 1980s, technologic advancements in imaging quality and digital storage have resulted in bedside ultrasound equipment that is both portable and powerful. Its use in the ICU results from recognition of its value for procedure guidance, interaction with cardiac intensivists in specialty ICUs, and shared interest from other clinical specialties such as emergency medicine. Ultrasound is emerging as standard of care for some ICU

procedures and is increasingly recognized as a valuable diagnostic tool. Nonprocedural bedside ultrasound applications performed by intensivists contrasts with traditional diagnostic imaging in that it is often interpreted at the bedside, occurs synchronously with management decisions, and is readily used by the bedside clinician for serial assessment. In this sense, a clinician-operated exam is more focused on assisting the direct and immediate delivery of care, whereas diagnostic imaging by radiologists and cardiologists emphasizes optimizing study detail and longitudinal assessment.

Ultrasound Physics and Basics of Image Optimization

The physical principles that make ultrasound possible are well described. Ultrasound energy is transmitted in sound waves through substances at a frequency >20 kHz, beyond the range of human hearing. Probes used for bedside ultrasound typically use energies in the range of 1 to 20 MHz or more. Ultrasound impulses are transmitted in a coordinated manner from an array of piezoelectric elements in a transducer aimed at a target of interest. Reflected sound from tissue and interfaces between substances of differing density is received by the same piezoelectric array. Based on known speeds of ultrasound in tissue as well as image processing by the ultrasound device, a two-dimensional image is generated and cycled over time to compose a continuous video or cine. Variability in tissue sound velocity and attenuation properties including refraction, reflection, absorption, or scattering of returning ultrasound energy may introduce artifact in images (Fig. 20.1).[1]

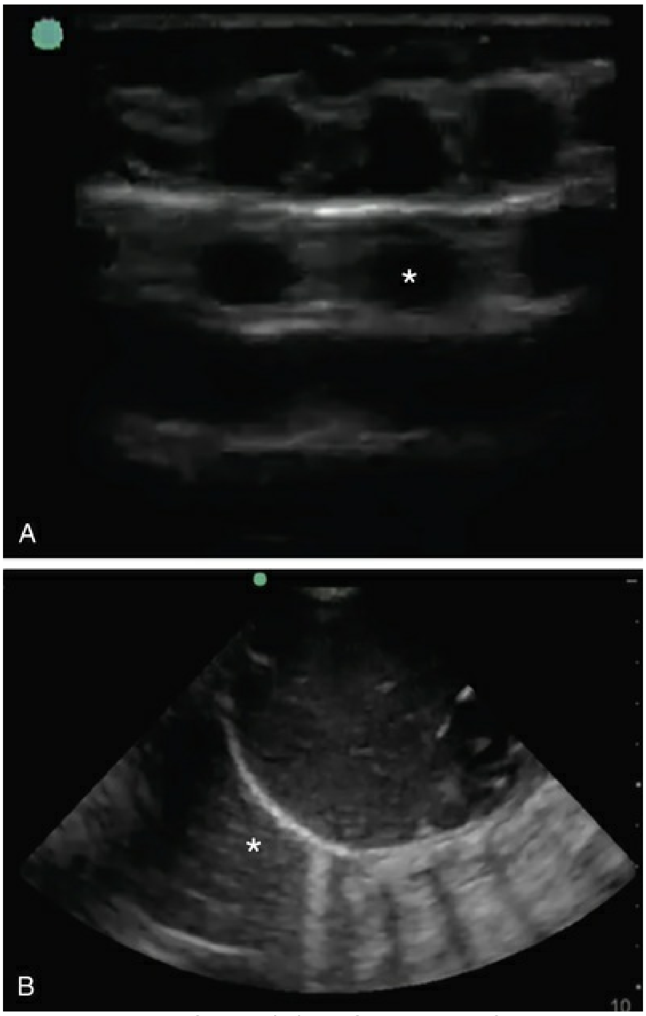

FIG. 20.1 Ultrasound artifacts. (A) Reflection artifact across the pleural line (*). (B) Mirror artifact across a diaphragm (*).

A portion of image quality is naturally machine dependent, and a variety of parameters are adjustable for image optimization to reduce diagnostic error. Image size modification tools include depth, zoom, and scan area. Though a wide and deep scan area permits capture of a large field of view, short depth or high zoom factor facilitates imaging of small or superficial structures (Fig. 20.2).

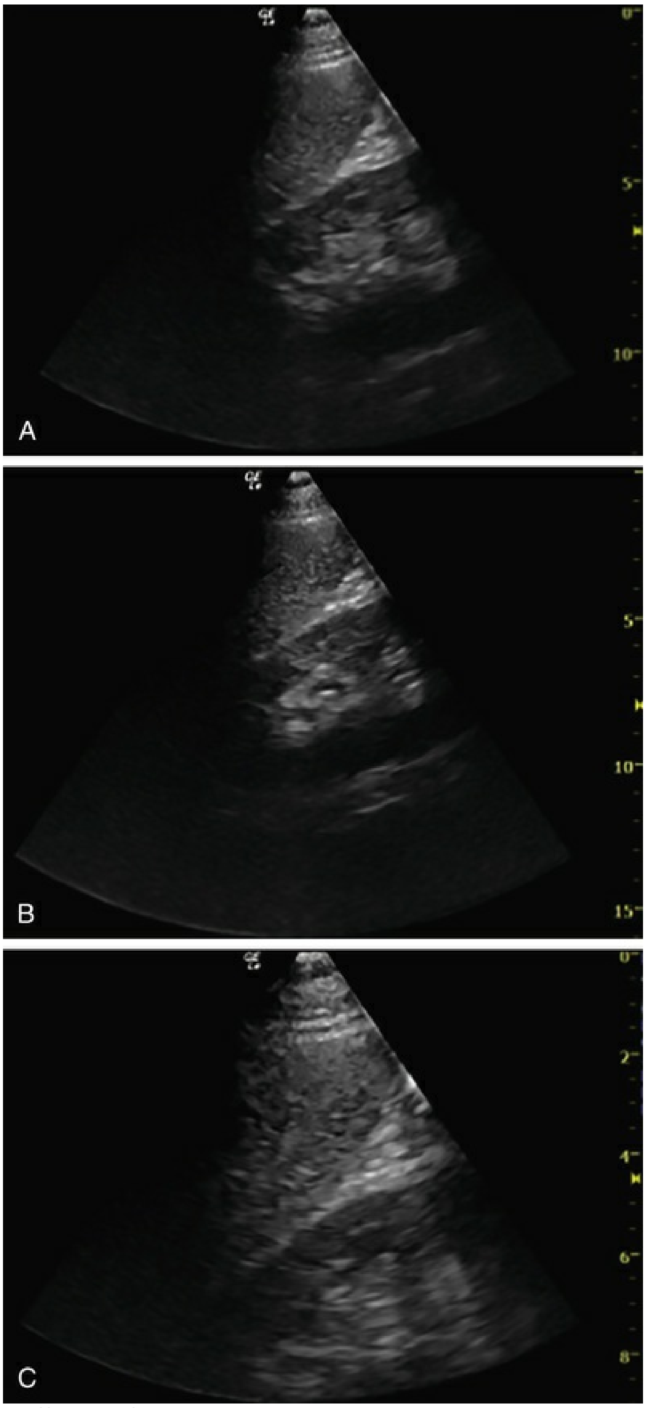

FIG. 20.2 Effects of depth on ultrasound image with B demonstrating same image as A at greater depth and C at shallower depth than A.

Gain is also an important setting for image optimization and can be adjusted in several ways. Gain affects the sensitivity of the machine to returning ultrasound energy. Returning ultrasound energy is attenuated as it passes through tissue. Time to return of reflected ultrasound energy determines depth of visualized structures rendered on the screen, and time-gain compensation settings can be adjusted to emphasize gain at different depths based on when the return signal reaches the transducer. On various machines these may appear as sliding controls or knobs that control near and far gain. At the bedside, gain is adjusted relative to ambient room lighting so that relevant pathology can be visualized (Fig. 20.3).

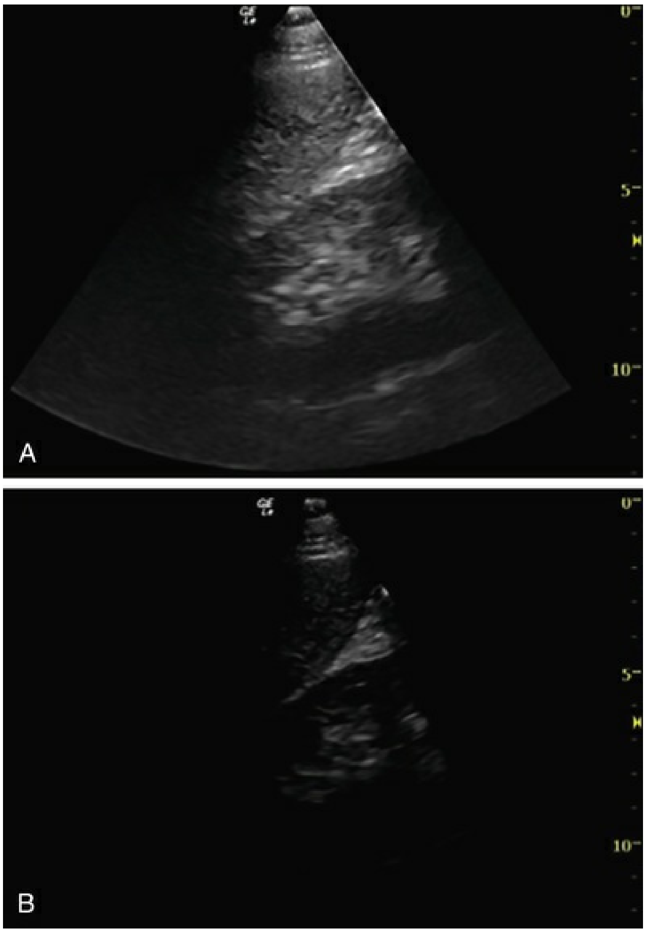

FIG. 20.3 Effects of gain on ultrasound image with B demonstrating same image as A at lower gain.

Frequency is an adjustable control that also affects image quality. Higher ultrasound frequencies allow for higher resolution imaging as a function of improved spatial discrimination of structures. Higher frequencies also result in poorer imaging of deep structures due to signal attenuation; conversely, lower frequency imaging can identify deeper structures at the expense of image resolution (Fig. 20.4). Some devices permit use of harmonic frequencies that can improve image quality of deep structures. In this mode, the machine only interprets frequencies of reflected sound that arrive at multiples of the fundamental transmitted frequency.

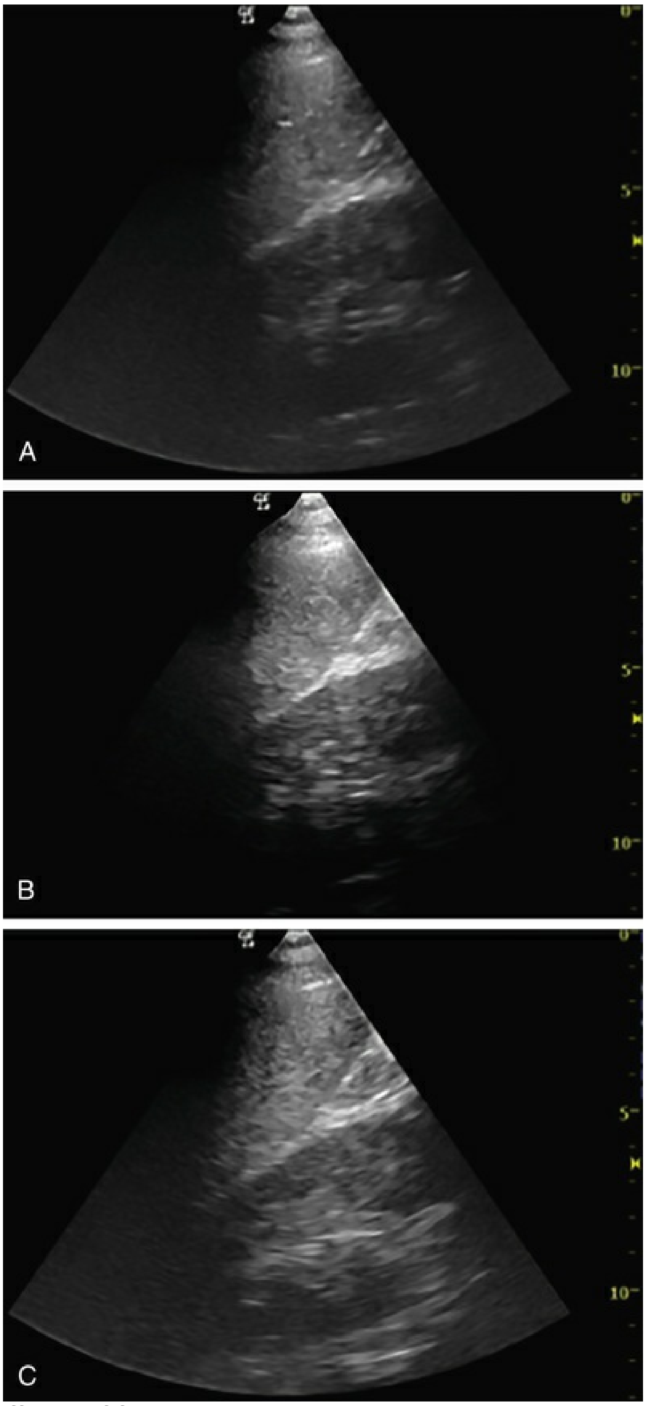

FIG. 20.4 Effects of frequency on ultrasound image with B demonstrating same image as A at higher frequency and C at lower frequency than A.

Doppler ultrasound is used in a variety of procedural and diagnostic applications to derive the speed of moving structures in the body, blood flow being a common target. Using color flow Doppler in vascular imaging, ultrasound machines color code areas on the two-dimensional image where tissue and fluid are moving: Returning reflected ultrasound frequency is either Doppler shifted higher (movement toward the transducer) or lower (movement away from the transducer). In the human body this can correspond not only to blood but also to the motion of fluid in the bladder and other potential spaces. Pulsed wave Doppler samples a small area of the screen for Doppler data that are then plotted along a velocity/time

scale (Fig. 20.5). Doppler is most useful when the direction of blood flow is parallel to the ultrasound beam. In instances where the flow is not parallel, the angle is corrected by multiplying the velocity sampled in the area of interest by the cosine of the angle of the incident ultrasound beam to fluid flow. This correction only evaluates the angle within the plane of the ultrasound beam. If the flow travels out of plane of the ultrasound beam, accurate measurements cannot be rectified with the correction function. For these reasons, use of angle correction is typically limited to approximately 30 to 45 degrees. By convention, in echocardiography angle correction is not used because of the difficulty in matching beam angles to nonlaminar flows in the heart.

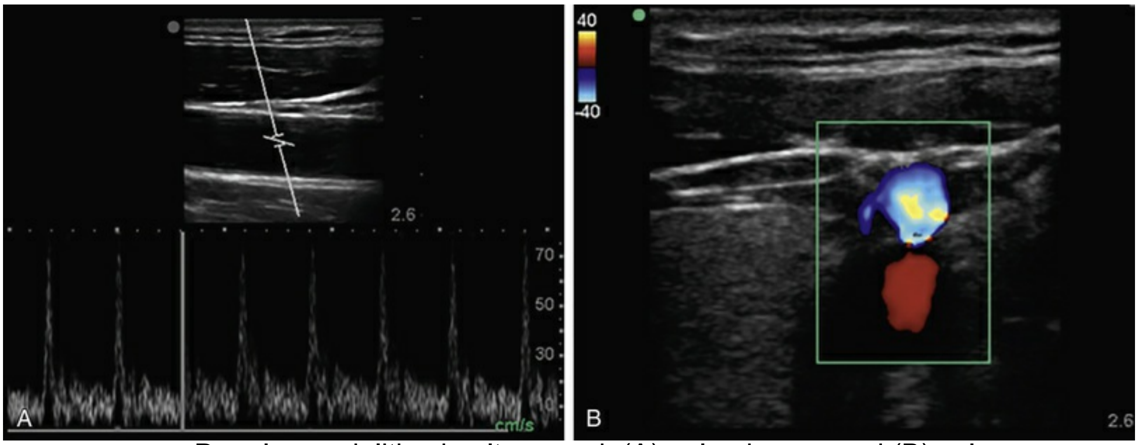

FIG. 20.5 Doppler modalities in ultrasound; (A) pulsed wave and (B) color flow Doppler.

Power Doppler displays amplitude of echoes from moving cells and is less angle dependent than traditional Doppler, thereby permitting improved visualization of vessel branching. For this reason, power Doppler can be a useful modality for vessel identification in procedure guidance. Power Doppler is typically displayed without directionality as seen in color flow Doppler; however, some machines permit superimposed directional color flow data.

M-mode ultrasound graphs the received ultrasound signal along a one-dimensional beam over time. This is useful for tracking objects in motion to quantify and characterize their movement (Fig. 20.6). Examples of M-mode applications include assessing respiratory variation of the inferior vena cava (IVC), calculating a left ventricular shortening fraction, and evaluating diaphragmatic excursion. When using M-mode, it is important that the operator's scanning hand be motionless because operator movement will be captured on the M-mode tracing as well.

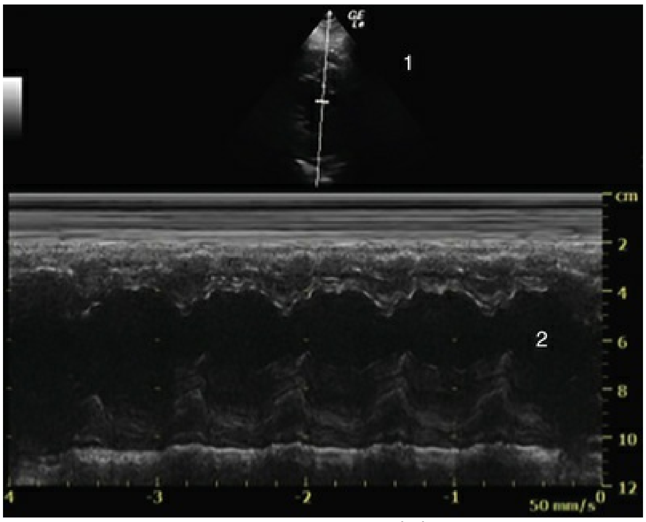

FIG. 20.6 M-mode imaging in ultrasound. (1) Two-dimensional image for cursor targeting. (2) M-mode tracing.

Sweep speed is an important machine setting for M-mode and pulsed wave Doppler where data are plotted against time. Sweep speed is defined as the speed at which the data tracing is graphed on the screen. In some instances a faster sweep speed is necessary to reduce the amount of time displayed on the screen, thereby "stretching" the tracing so that finer details of movement are captured. This is helpful in echocardiography with a tachycardic heart so that cardiac motion is more easily discerned. Conversely, slowing sweep speed may be helpful in compressing more data into the screen (Fig. 20.7). Slowing sweep speed might be necessary for visualizing changes in cardiac ejection or inflow velocities over a respiratory cycle.

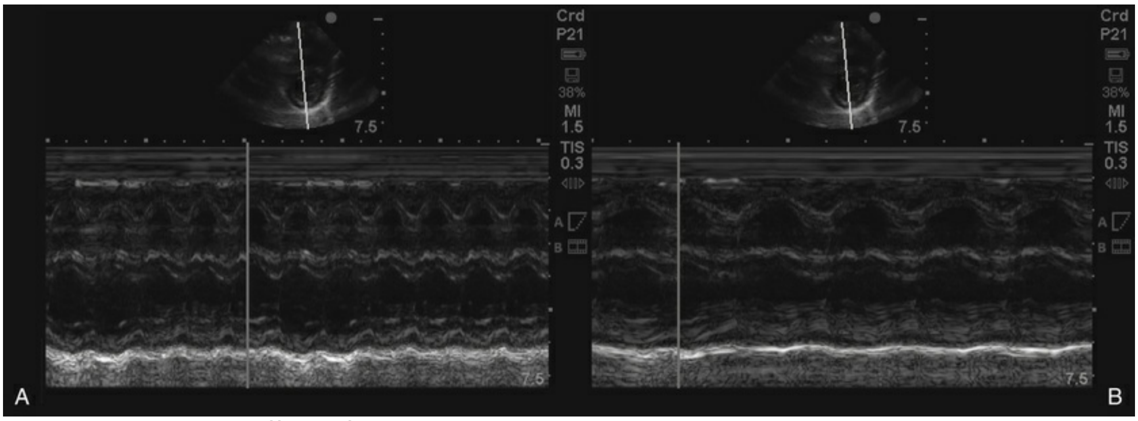

FIG. 20.7 Effect of sweep speed on time-based modalities. In this example of M-mode imaging, the image in A is running at a slower sweep speed than the image in B.

Transducers

Ultrasound transducers appear in a multitude of configurations that serve different specialized functions. They are largely divided into higher frequency linear array probes and lower frequency sector type probes, with occasional exceptions.

Linear array transducers are a mainstay of procedural guidance for intensivists and other clinical interventionalists using ultrasound (Fig. 20.8). They are configured with an array of parallel-oriented piezoelectric elements designed to image a field of tissue below the probe at close proximity to the skin. These probes also tend to emit higher frequencies (7 MHz or above) to visualize the region of interest at high resolution, with some small structure probes operating above 20 MHz. Linear array transducers are optimal for procedural guidance because needle localization is easier with their wide, shallow, and high-resolution field of view. Linear array transducers are also well suited to diagnostic imaging at shallow depths where higher resolution is preferred. Examples include thoracic imaging and vascular imaging. Linear arrays range in size and shape. In addition to conventional arrays in which the transducer face forms the end of the handpiece, linear transducers also include “hockey-stick”–shaped vascular probes, originally designed with improved ergonomics for carotid imaging but also useful for peripheral vascular procedures in children.

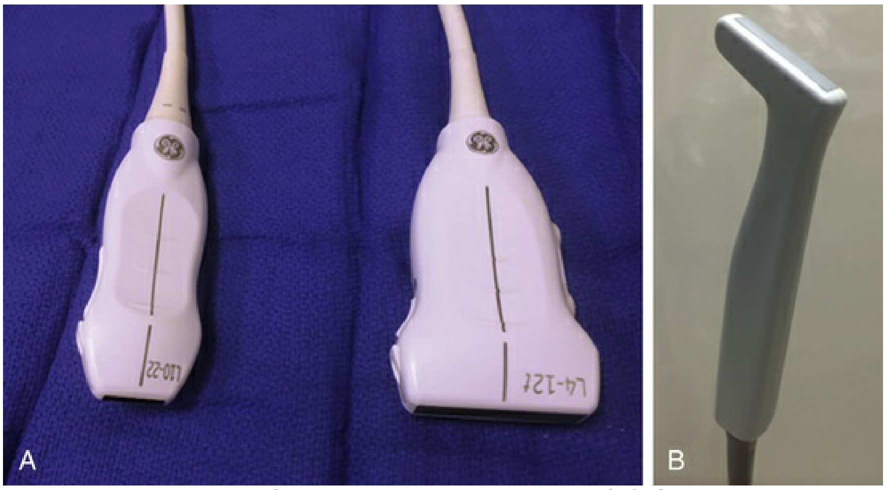

FIG. 20.8 Examples of linear array transducers. (A) Conventional linear array probes. (B) Carotid vascular or “hockey-stick” probe.

Sector-type transducers encompass phased array transducers and curvilinear transducers. The sector term refers to the image generated by the concave array appearing as a wedge-shaped sector on the ultrasound screen. Phased array transducers are low-frequency devices and have a small footprint on the skin, designed for deeper wide field imaging at depth (Fig. 20.9). Because these probes are largely used in cardiac imaging, the ultrasound hardware is optimized for fast frame-rate video at the expense of image resolution. Because of the small footprint and low frequency, these probes are also optimally suited for transcranial imaging for Doppler flow measurements of the cerebral arteries. This type of imaging requires a low fundamental frequency of approximately 1 MHz, with most probes ranging between 1 and 6 MHz. These probes can also be used for diagnostic imaging in the abdomen, particularly in infants and young children.

FIG. 20.9 Examples of phased array transducers.

Curvilinear transducers operate at the same to slightly higher frequency (1-12 MHz) than phased array transducers and are engineered for improved image resolution at the expense of a slower frame rate. For this reason they excel at looking at relatively nonmobile structures such as the abdomen and its vasculature. Large curvilinear probes are often too large for children and therefore smaller radius microconvex curvilinear probes are preferred. These probes are also used for cranial ultrasound in infants due to their higher frequency and small footprint. Within the ICU, their higher resolution and footprint that is slightly wider than that of a phased array transducer also make them useful for procedure guidance, particularly for vascular access and regional anesthesia. In addition, they may facilitate visualizing the lung and thoracic structures.

Procedural Guidance

Long before entering the ICU, ultrasound became a mainstay for procedural guidance in the operating theater and interventional radiology suite. In the hands of intensivists, ultrasound has proved to be a useful adjunct in vascular access, increasing first-pass success and reducing adverse events during central venous catheter (CVC) insertion in a number of large series.[1-4] Though the majority of ultrasound trials for vascular access have been conducted with trainees likely less familiar with landmark methods for CVC insertion, the preponderance of the primarily adult evidence supporting ultrasound guidance for internal jugular vein CVC cannulation has changed the procedure such that most practice environments would not have sufficient equipoise to have a landmark-only arm for a randomized trial. Although it appears that ultrasound guidance does improve safe vascular access, its use is a skill that requires training and practice. Novice providers should practice procedures with skilled operators before attempting them independently.

Before attempting procedural cannulation of a venous structure, it is important to identify surrounding arterial structures and demonstrate venous patency. Veins should be compressible and without distinct arterial pulsatility.

Similarly to techniques used during vascular examination of extremities, maneuvers for identification of vessel patency are helpful for targeting veins for cannulation. The primary and most reliable method is observing for compressibility

of the venous structure and absence of pulsatility. Methods used in the vascular laboratory that can help identify a vessel include use of Doppler ultrasound to identify vessel flow and augmentation of vascular flow by squeezing the muscular extremity distal to the area being examined with ultrasound (eg, the calf when examining the common femoral vein). It is important to recognize, however, that in the setting of pulmonary hypertension, pulsatile venous flow can confound differentiation between vein and artery, as it can cause pulsatile distention as well as reversal of blood flow in the vein. Though this finding is most pronounced in patients who carry a known diagnosis of severe idiopathic pulmonary hypertension, it can also be seen in patients with acquired pulmonary hypertension from increased intrathoracic pressure or cardiogenic shock. Augmentation of flow is also not entirely reliable; this technique will show vascular flow in the setting of partial vessel obstruction as well, if flow can get around the obstruction. Additionally, a color Doppler signal may not match vessel dimensions because the signal may "bloom" or contract depending on the machine's Doppler gain setting.

In the event that these maneuvers do not demonstrate patency, a vessel may no longer be continuous due to sclerosis or thrombosis. Thrombi may or may not appear echogenic and may or may not obstruct venous flow. When identified they occupy space in the vessel lumen and are observed to obstruct venous flow and resist compression. Doppler modalities for identifying vessel occlusion are well described but have limited utility when thrombi are partially occlusive or in shock states when flow is very low.

Varying approaches to central vessel cannulation using ultrasound exist. Dynamic approaches to the central veins include the transverse (Fig. 20.10A) or the longitudinal (Fig. 20.10B) planes relative to the vessel. An advantage of the transverse approach is that it improves lateral steering of the needle to avoid arterial puncture. A disadvantage is that needle tip identification is harder, because only a cross section of the needle shaft is visualized. Identification of the needle tip is crucial for successful access and prevention of inadvertent injury, and it is performed by sliding the probe and staying over the needle tip throughout the procedure. This technique will avoid inadvertent puncture of deeper structures (ie, the pleura or carotid artery in internal jugular venous cannulation). The longitudinal approach has reciprocal advantages and disadvantages, facilitating observation of the advancing needle tip without moving the probe but losing lateral aiming capability. For these reasons, transverse visualization of the vessels is often more intuitive and most frequently taught to novice practitioners. *Static* ultrasound-guided central venous access uses the transducer to identify the vessel followed by marking of the site for needle puncture without direct ultrasound visualization of the needle during the attempted cannulation. This permits use of both hands for the technical performance of the procedure; however, patient positioning or physiology may change prior to venipuncture, rendering the mark inaccurate. Static guidance has been shown to be inferior to the active ultrasound guidance or so-called dynamic technique.[5]

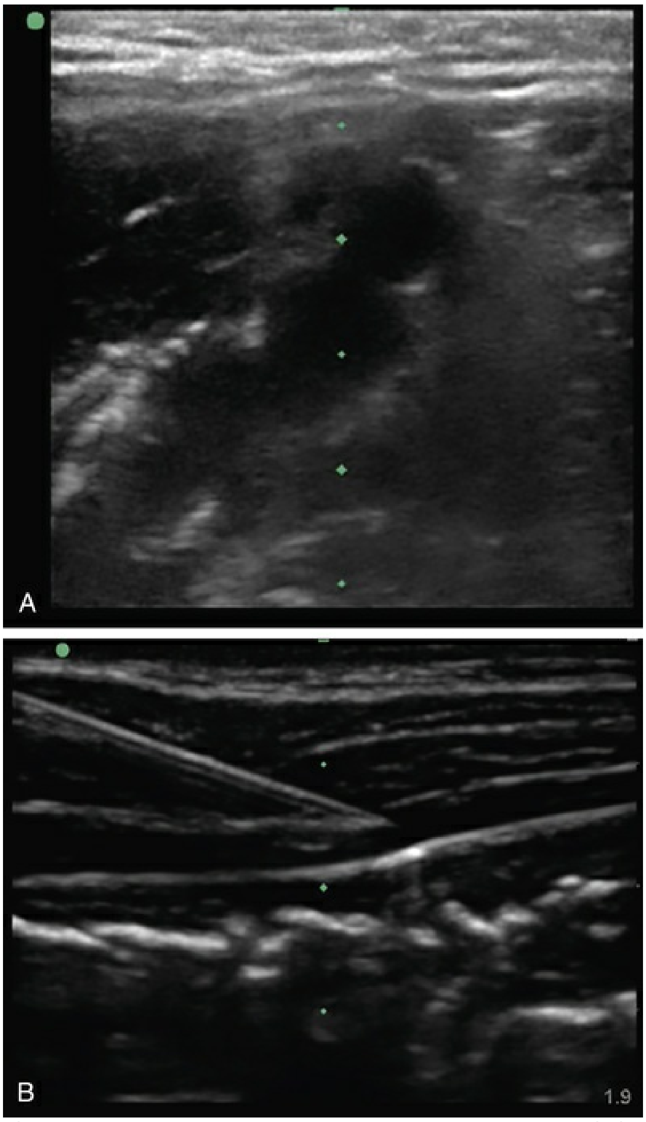

FIG. 20.10 Sonographic approaches to vascular access. (A) Transverse plane. (B) Longitudinal plane.

Though most existing literature focuses on internal jugular venous access, experience describing other vessel access using ultrasound guidance has been published. There is limited adult patient experience reported on the placement of CVCs in the subclavian vein.[6,7] Ultrasound guidance for subclavian access may be stymied by relative probe to patient size issues in pediatric patients. In the longitudinal orientation, the transducer occupies the majority of the skin in the infraclavicular space and limits the area for target insertion. A number of authors have described a supraclavicular approach to the subclavian or brachiocephalic vein.[8-12] This is also approached using a longitudinal transducer orientation to the vessel and can be difficult in children for whom the length of the transducer displaces the needle insertion rather distal to the clavicle. In addition, the technique's dependence on the longitudinal approach makes it less accessible to novice learners. Use of a microconvex array to place a subclavian CVC is promising as a future adjunct for the procedure.[13]

Ultrasound guidance for femoral vein CVC placement remains contentious as the existing literature is limited methodologically and includes only small series or

series that include femoral cannulation mixed with other catheterization sites.[14-16] Studies that compare different ultrasound approaches or ultrasound- versus landmark-guided approaches to femoral vein cannulation by pediatric intensivists are lacking and seem indicated, given different characteristics of the femoral vein in children compared to adults.[17-19]

The literature includes few descriptions of central axillary vein CVCs, but this site can be useful for patients with limited options for central access. When inserted in the axillary vein at a position in or distal to the axilla, the catheter takes a similar course to subclavian CVCs. A longer catheter length is necessary so that it reaches from the axilla to the turn of the brachiocephalic vein into the superior vena cava (SVC). In contrast to other CVCs, the redundancy of axillary tissues complicates venipuncture, and ultrasound guidance seems especially beneficial.

Outside of central veins, ultrasound has also been useful for peripheral IV access and arterial access. For patients with difficult peripheral access, ultrasound facilitates targeting and site selection leading to successful IV placement.[20] Ultrasound can identify sites difficult to detect from the surface, particularly collateral vessels that may become engorged due to obstruction of previously cannulated veins. An important consideration is vessel depth, because deep infiltrates are not as readily recognized as shallow ones, resulting in soft tissue injury and potential serious safety events. [21] Intravenous catheters exceeding an inch in length are useful to access deeper vessels and to increase maximize length of catheter within the vascular lumen. Their insertion benefits from placement in veins with sufficiently long straight courses. Deeper vessels require a steeper angle of insertion, and this increases the risk of penetrating the back wall of the vessel. Following the threading of the IV catheter into the vein under ultrasound visualization may help ameliorate this effect, as the operator can keep the device off of the back wall of the vessel. For these reasons, IVs deeper than a centimeter from the skin surface are poor candidate vessels.

A number of series have been published on ultrasound guidance for peripheral arterial access. Though historically the arterial pulse has been relied on for arterial catheterization, both adult[22] and pediatric studies[23] demonstrate that ultrasound guidance using methods similar to venous procedures facilitates arterial access.

Ultrasound can also help identify catheter position after CVC placement. Direct visualization of other CVCs in the IVC in addition to umbilical catheters is possible in patients.[24-26] However, identifying upper extremity CVCs is difficult because views of the superior cavoatrial junction are obstructed by lung artifact in older children and adults.[27-29] Another technique that has been demonstrated to verify central venous catheter position is use of agitated saline.[30,31] Agitated saline is produced by rapidly flushing approximately 0.5 to 1 mL of air and 9 to 9.5 mL of saline between two 10-mL syringes attached to a stopcock connected to the CVC until the distribution of small bubbles in the saline appears as homogenous as possible. At this time the saline is steadily, quickly, and carefully flushed into the patient such that the contrast is delivered promptly, though large bubbles are not injected. Agitated saline opacifies vascular structures and indicates continuity of the catheter within the proximal vessel or heart. Failure of the bubbles to appear in the venous space suggests that the catheter is not in the correct vessel. Pitfalls in this technique include slow injection, where bubbles may not reach the heart, and the presence of shunting, which could also diminish return of bubbles to the area being

examined with ultrasound. Agitated saline techniques should be used with acceptance that the bubbles might travel into the systemic circulation, where there is a small risk that they could obstruct distal organ perfusion. These methods may ultimately decrease the need for radiography.

Umbilical access can also be facilitated by ultrasound in neonatal patients who may be in the pediatric ICU for specialized therapies such as advanced cardiac care or extracorporeal membrane oxygenation (ECMO).[24,25] Umbilical catheters can be placed using sagittal positioning of a small curvilinear or phased array transducer over the inferior vena cava as it enters the right atrium. Confirmation of tip position at the IVC–right ventricular (RA) junction is possible using this method because catheters are echogenic. This technique can be employed in umbilical arterial catheter placement by identifying the catheter in the descending aorta at the level of the diaphragm.

Drainage Procedures

Ultrasound is a useful adjunct to thoracentesis and thoracostomy. Pleural fluid collections are highly amenable to ultrasound interrogation. Simple effusions appear as an enclosed dark anechoic space sharply differentiated from surrounding tissues and often with underlying consolidated lung appearing to float within the fluid. Ultrasound is useful for characterizing effusion complexity: Proteinaceous septations and debris appear echogenic within the effusion.

Effusions can be visualized from several locations. During a pleural exam, using a linear array, effusions are recognizable as a dark anechoic space below the parietal pleura. Effusion can also be seen on echocardiographic views, particularly those capturing the dependent areas of the lower thorax such as subcostal or apical views (Fig. 20.11A). Additionally pleural effusion can be seen in abdominal exams of the right and left upper quadrant if the view captures the posterior aspects of the diaphragm. In these cases the effusion appears as an anechoic space cephalad to the diaphragm. An advantage of imaging an effusion using a phased array or curvilinear probe is that a large portion of the effusion tends to be visible in the far field of the sonographic sector, allowing identification of a deep effusion pocket, its extent, and its complexity (Fig. 20.11B). Color Doppler ultrasound may assist with effusion identification because its motion within the potential space will be detectable.

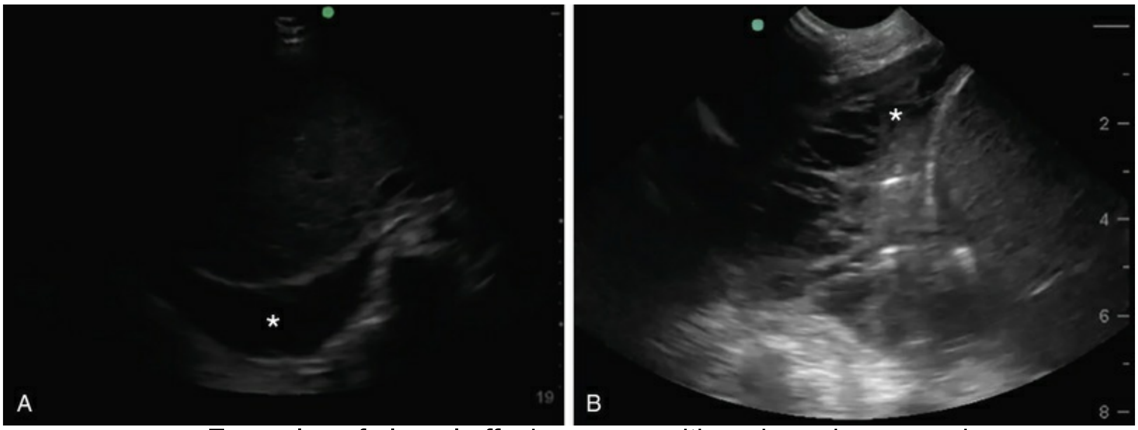

FIG. 20.11 Examples of pleural effusions seen with a phased array probe. (A) Simple effusion (*). (B) complex effusion (*).

Pleural fluid collections can be easily targeted for drainage using ultrasound to ensure safe needle insertion above the diaphragm. Though dynamic ultrasound guidance can be used during the drainage of an effusion, the *static* technique (ie, marking the location for needle insertion) simplifies the procedure without exposing the patient to increased procedural risk. There is presently no evidence to suggest clear superiority of one technique over another.

Thoracostomy tubes can also be identified in the effusion space, but they are less visible once fluid is drained. Prior to attachment of a thoracostomy tube to suction, visualization of the effusion space and position of the chest tube within can sometimes help determining whether the tube travels anterior or posterior to the lung.

Abdominal fluid collections are also characterized as simple or complex, and drainage of the peritoneal space is possible using ultrasound guidance. An important consideration in performing paracentesis is locating (and avoiding) the inferior epigastric arteries traveling from the iliac arteries cephalad along the inside of the anterior abdominal wall at the lateral edge of the rectus abdominis muscle. These vessels are identifiable on ultrasound and the machine can assist in planning a safe needle insertion.

With ultrasound, paracentesis is most easily performed from the lateral approach. After appropriately preparing the patient and identifying fluid for drainage, the arteries are identified. Rather than performing a traditional z track entry, the needle can be introduced obliquely into the peritoneal cavity with the probe oriented longitudinally over the needle for dynamic guidance (Fig. 20.12). The oblique track helps reduce the chance of leakage, is easier under ultrasound than the z track, and allows direct visualization of needle entry into the peritoneum to avoid underlying solid and hollow organ puncture. A temporary catheter can then be placed using the Seldinger technique for either one-time or ongoing drainage of ascites fluid.

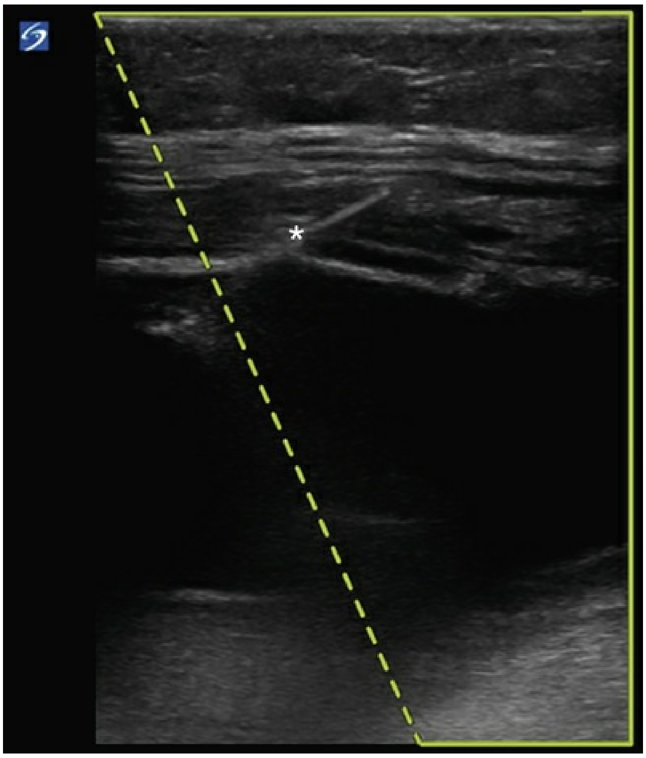

FIG. 20.12 Ultrasound-guided paracentesis. An asterisk (*) identifies the needle.

Lumbar Puncture

Ultrasound-guided lumbar puncture provides limited advantage over landmark-based techniques in children as demonstrated in the literature,[32,33] though some hypothesize it is beneficial in patients who have difficult landmarks, such as older and obese patients[34] and perhaps children with spine abnormalities. Such patients can benefit from ultrasound-guided lumbar puncture due to difficulty in determining surface landmarks and insertion depth secondary to lumbar muscularity or adipose tissue. The technique can be performed under ultrasound visualization, but due to the near-perpendicular angle of needle insertion into the skin, the procedure is easier under static guidance using insertion markings (Fig. 20.13). This process involves visualizing the spine in two planes, both sagittally along the spine to identify the appropriate entry level and axially across it to center insertion in the midline. Additionally views of the spine can be used for measuring angle and depth of needle insertion to reach the dural space so that an appropriate needle can be selected.

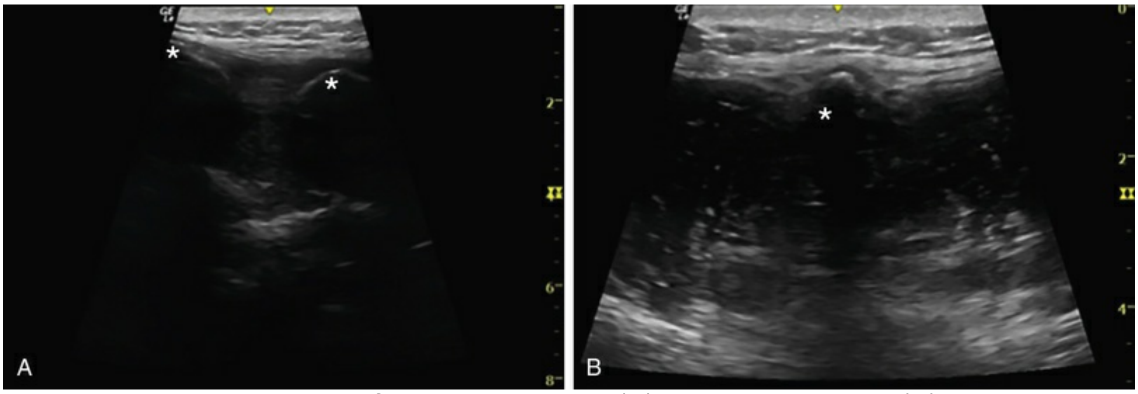

FIG. 20.13 Views of the lumbar spine. (A) Longitudinal view. (B) Transverse view. Spinous processes are indicated by *asterisks*.

Diagnostic Modalities

Pulmonary Ultrasound

Historically, pulmonary ultrasound has been considered impractical due to air-filled structures impeding ultrasound transmission.[35] Yet ultrasound images are produced within the thoracic cavity by the complex interaction of the ultrasound beam with interfaces between air- and water-filled structures. Seminal work done by intensivists examining the lungs of critically ill adults and children led to descriptions of pulmonary artifact patterns that reflect lung pathology.[36]

In the child, the patient's age can affect visualization of the thoracic cavity. Infants have excellent windows for thoracic visualization because of shallow imaging depths to reach the pleural space, higher body water content, and limited thoracic cage ossification. As children age, their imaging windows may become more difficult as a result of development, including increasing ossification and decreasing body water content, though imaging windows remain largely obtainable. If areas of the pleura are difficult to visualize due to ribs, rotating the probe parallel to the ribs within the intercostal space can improve the view. Lung motion is still appreciated as artifacts across the pleural plane. Alternatively a microconvex or phased array transducer can be used to see the pleural line, though these lower frequency probes often perform better in evaluating deep structures.

Thoracic ultrasound of the pleural space identifies overlying skin and soft tissue nearest to the probe, followed by deeper rib and intercostal structures, and then the pleural space. The visceral pleura slides against the parietal pleura through a thin and often invisible layer of normal pleural fluid.

Though the exact physiologic mechanisms underlying ultrasound lung artifacts is not definitively known, their similarity to artifactual findings associated with pathology in other organ systems and associations with pathology suggest their origins. Reverberation artifacts that replicate the pleural line at regular intervals from proximal to distal field are called A-lines and often appear in the center of the ultrasound beam. These can appear regardless of pathology or whether tissue or air is underlying the parietal pleura, and therefore they need only be recognized as artifacts in the image. B-lines and Z-lines are generated radially from interfaces near the pleural line and appear to pierce through the lung parenchyma. B-lines reach the

end of the viewable sector and obliterate A-lines, whereas Z-lines are limited reverberatory extensions from the pleural line (Fig. 20.14).

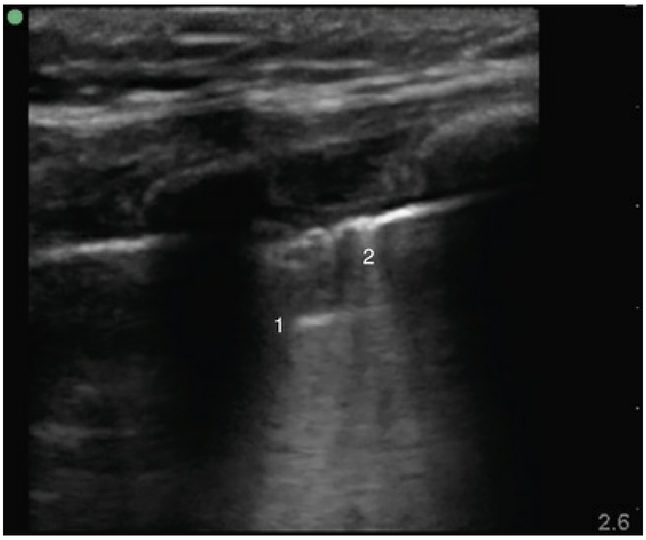

FIG. 20.14 Ultrasound of the thorax using a linear probe. (1) A-line. (2) B-line.

A pattern of increased B-lines suggests increased interstitial lung water. In the adult population this is consistent with pulmonary edema,[37] and it is reasonable to infer that it would bear similar implication in children. However, studies also suggest that B-lines indicate the presence of bronchiolitis in children in the emergency room setting.[38] Further elucidation of the significance of B-line patterns in critically ill children is lacking.

B-lines in children may also represent lung consolidation. Consolidated lung appears increasingly granular with the appearance of liver-like parenchyma, commonly referred to as *hepatization* due to the augmented visibility of consolidated lung parenchyma and vascular architecture appearing similar to hepatic structures. In the case of infectious pneumonias, diffuse geographic areas of consolidation, air, and necrosis may develop, resulting in what some authors term the *shred sign*. The diagnostic value of these lung consolidation patterns in critically ill children has not been well quantified to date.

Identification of pneumothorax with ultrasound has been described[37] as a dissociation of the visceral from parietal pleura by ultrasound-obstructing air, such that the parietal pleura is no longer visible (Fig. 20.15). Loss of pleural sliding is indicative of pneumothorax, and identification of the limit of a pneumothorax as the point where pleural sliding abuts an area where it is absent is described as the lung point. Identification of the lung point is highly specific for pneumothorax.[39] M-mode ultrasound is also useful for identification of pneumothorax. Placement of the M-mode cursor through the pleural surface characterizes movement of the lung parenchyma as a "granular" textured echogenic area distal to the pleural line. When contrasted with the more horizontal linear pattern of the proximal chest wall, this assumes a seashore-like appearance (Fig. 20.15B). When the M-mode cursor overlays pneumothorax, no lung parenchyma movement is seen, and the entire M-mode tracing over time appears to be a pattern of horizontal lines, otherwise described as a

barcode or *stratosphere* sign (Fig. 20.15D).

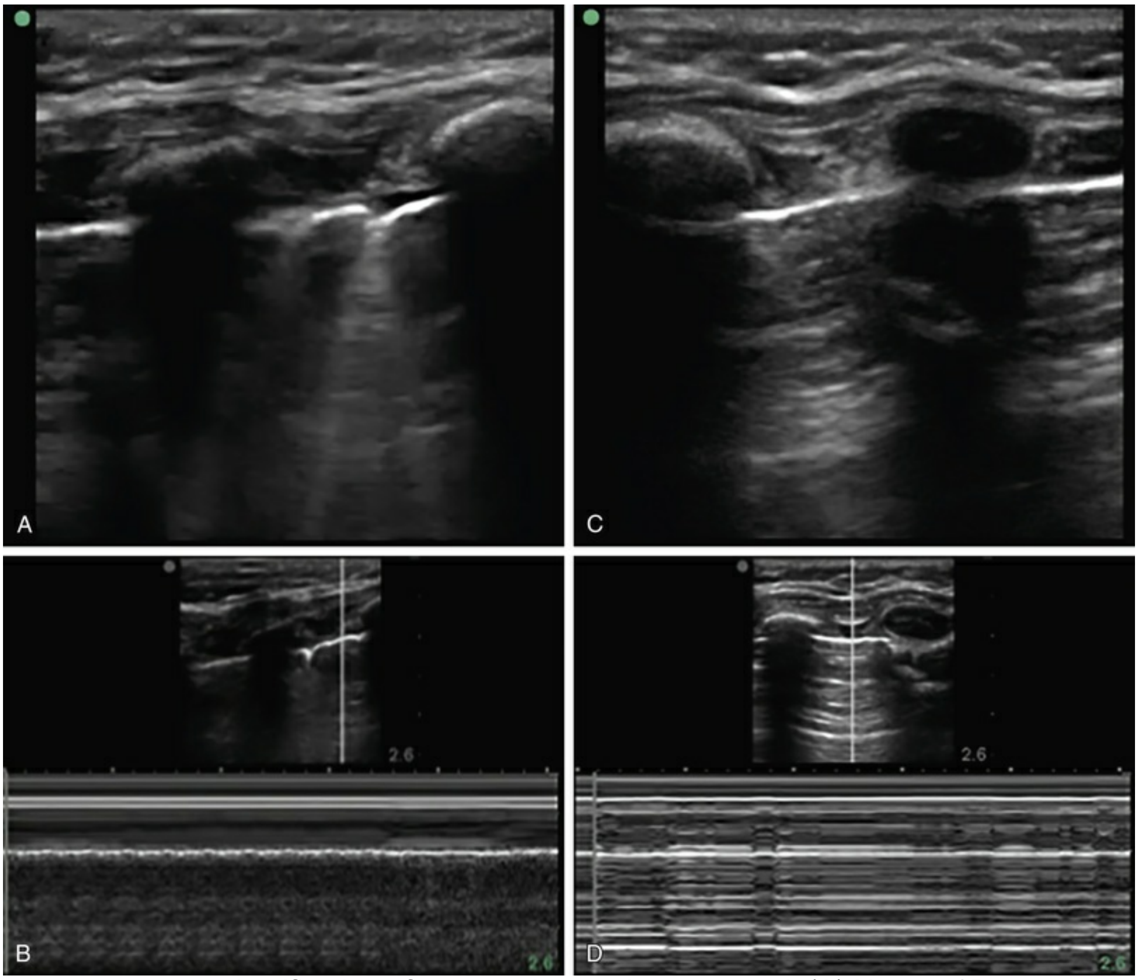

FIG. 20.15 Identification of pneumothorax via ultrasound. (A) Normal 2D lung ultrasound image. (B) Corresponding M-mode image. (C) Note lack of B-lines in pneumothorax in 2D image. (D) Corresponding pneumothorax M-mode image.

Ultrasound views of the diaphragm can confirm tracheal placement of an endotracheal tube during intubation, though distance from the carina cannot be reliably determined in the older child. This is potentially useful in the management of a ventilated patient requiring rapid confirmation of tracheal placement such as in the case of a difficult airway patient for whom removal of the tube and reintubation could be dangerous. In this instance, subcostal views of the diaphragm capturing motion of each leaflet while the patient receives positive pressure breaths can be performed (Fig. 20.16). Confirmation that at least one leaflet moves with large positive pressure breaths will help verify that the tube is in the airway. Lack of excursion on one side might suggest main stem bronchus occlusion from secretions or inadvertent main stem bronchial intubation of the contralateral lung. This technique has been used to confirm tube placement in the operating theater[40] as well as in the pediatric emergency department,[41] though the distance between endotracheal tube (ETT) tip and carina cannot be accurately measured. In the neonatal population, the tube is visualizable in the sagittal plane from the

parasternal view typically used for evaluation of the aortic arch and pulmonary arteries. Dennington and colleagues were able to accurately gauge depth of ETT position in neonates with high accuracy.[42] In larger infants and older children, this technique has not been successful due to thoracic growth and ossification.

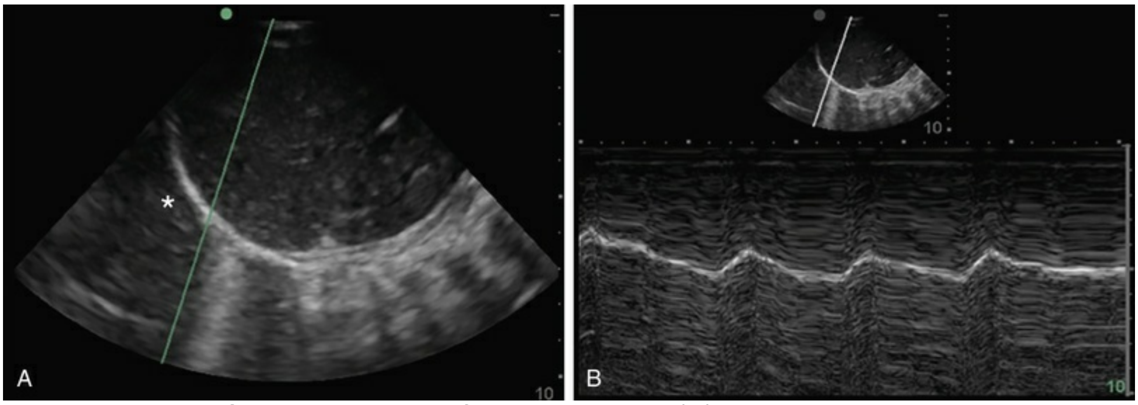

FIG. 20.16 Subcostal image of the diaphragm. (A) An asterisk indicates the diaphragm that is identifiable on M-mode imaging (B).

Use of diaphragm windows to assess diaphragm paresis has also been described.[43-46] In multiple series, assessment of spontaneous diaphragm excursion using ultrasound in the oblique coronal (described previously) or sagittal planes accurately demonstrates diaphragm paresis. One would expect it to be similarly useful for patients with diaphragm paralysis from a variety of causes including protracted neuromuscular blockade or intrinsic neuromuscular dysfunction.

Abdomen

Assessment of abdominal pathology is frequently confounded by nonspecific complaints, particularly in sedated patients. Ultrasound as a noninvasive technology has potential for evaluating abdominal pathology without the radiation exposure of CT. However, as is the case with pulmonary pathology, air within the abdominal cavity creates challenging obstacles to ultrasound interrogation (Fig. 20.17). When air causes artifacts, determining whether the air is within the peritoneum or in the bowel is difficult and is a limitation of abdominal ultrasonography. Air localized within the liver vasculature, as well as bowel wall hypervascularity, has been associated with necrotizing enterocolitis in the at-risk neonate.[47-49]

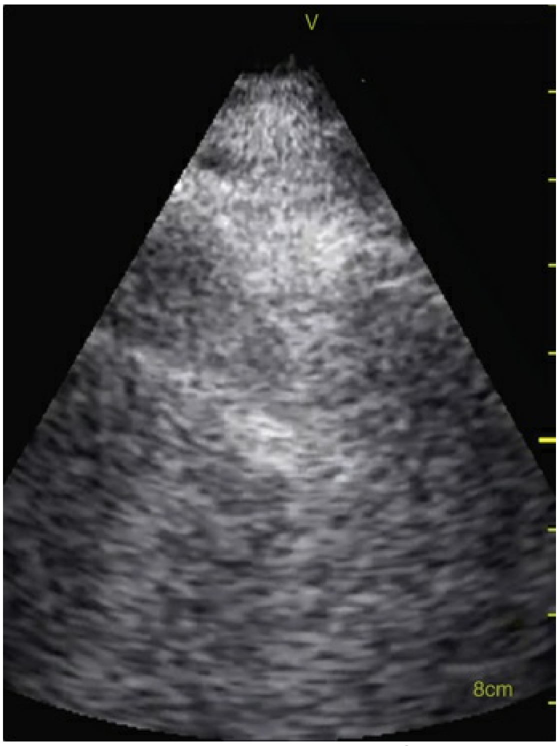

FIG. 20.17 Abdominal ultrasound with air interference obstructing view of abdominal contents.

Similarly, fluid in the abdomen can appear within or outside the intestinal lumen. The normal appearance of air artifact and stool is absent in fluid-filled ileus resulting in ultrasound visualization of distended, anechoic bowel loops. Peritoneal fluid as a result of ascites, hemorrhage, or peritoneal dialysis fluid is commonly seen in acute care settings. A focused assessment with sonography in trauma (FAST) is performed in four abdominal windows where dependent fluid could appear from a traumatic injury. The probe is usually a curvilinear or phased array transducer. The FAST exam is widely used in adult trauma resuscitation for identification of intraperitoneal fluid, likely either from hemorrhage or ruptured viscus.[50-52] Though some adult literature supports the FAST exam as a replacement for computed tomography of the abdomen and diagnostic peritoneal lavage, successful performance of the application depends on operator expertise and time from the event. In children, the sensitivity of the test is as poor as 52% in some series,[53] likely because solid organ injury in children may result in smaller areas of bleeding. Despite its poor sensitivity, it has demonstrated good specificity in pediatric trauma,[53-59] and the finding of unexpected fluid in a pediatric trauma patient is likely a sign of an intraperitoneal injury.

Right Upper Quadrant (Fig. 20.18A)

The hepatorenal recess (Morison's Pouch) is the most dependent part of the peritoneum in the supine patient. Fluid can be seen between the retroperitoneal kidney and the intraperitoneal liver or above the liver as well. The transducer is placed near or below the lower ribs of the thorax in the posterior axillary line to visualize the right kidney with the indicator directed toward the patient’s head. Fluid in the Morison's Pouch, inferior pole of the kidney, or the perihepatic space suggests intraperitoneal injury. The diaphragm is also seen in this view, and pleural

effusion or intrathoracic hemorrhage in the trauma setting can also be identified or suspected when a classic mirror artifact of liver due to diaphragm is not visualized. The probe is usually oriented coronally but can be oriented axially with respect to the patient, and the entire organ should be scanned. If views from the posterior axillary line are difficult, the right kidney can be visualized in the anterior sagittal plane by placing the transducer at the lower edge of the costal margin just lateral to the midclavicular line with the indicator pointed toward the patient's head. In this view the Morison's Pouch can be visualized through the liver.

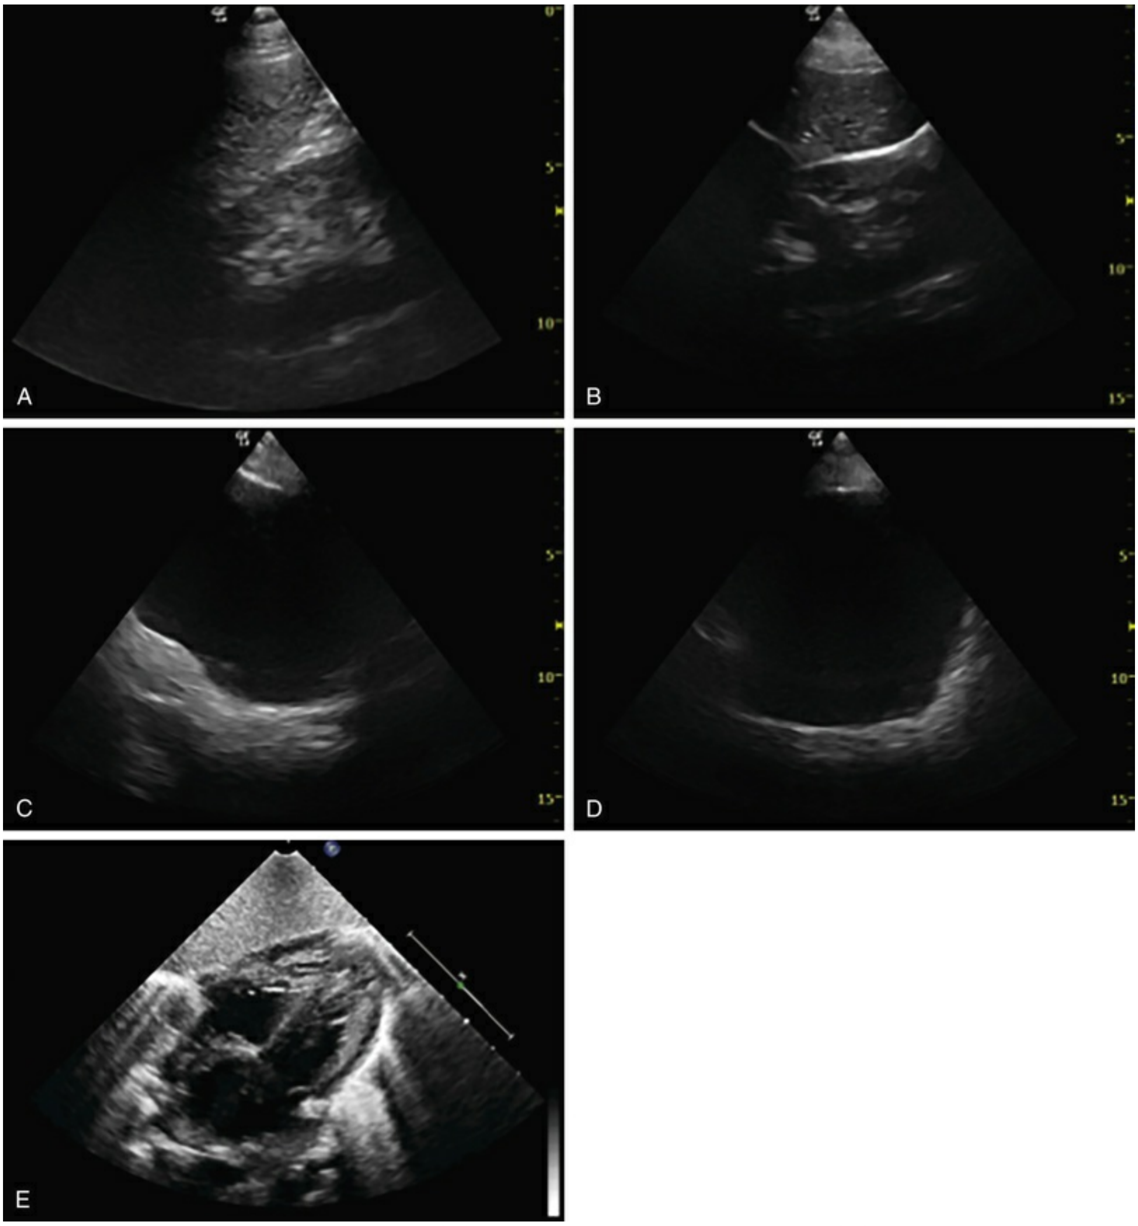

FIG. 20.18 The FAST exam. (A) Right upper quadrant view, (B) left upper quadrant view, (C) longitudinal and (D) transverse views of the bladder, and (E) subcostal cardiac view.

Left Upper Quadrant (Fig. 20.18B)

The splenorenal recess can be visualized from the left flank at the level of the posterior axillary line as well. It is visualized similarly to the view in the right with the probe indicator positioned toward the head for a coronal view of the kidney and surrounding spaces. Anterior windows are usually not feasible because of stomach contents. The left kidney is more cephalad in the abdomen than the right, and views from above the costal margin may be necessary. In this view pleural effusions can also be visualized.

Pelvis (Figs. 20.18C and D)

Particularly if a patient has been upright or inclined after trauma, fluid can accumulate in the pelvis in a manner not seen in the upper quadrants. As with visualization of the kidneys, the bladder can serve as an easily identifiable landmark from which to reference regional anatomy and discern pathology. The bladder is imaged in both the axial and sagittal planes. Fluid posterior to the bladder in the male or posterior to the bladder or uterus in the female patient suggests pathology.

Subcostal Cardiac (Fig. 20.18E)

The heart is visualized in the FAST scan from the subcostal margin below the xiphoid process, with the probe aimed toward the patient's left shoulder, and the indicator oriented toward the right flank if the machine remains set in a radiology convention setting with the screen indicator to the operator's left. The heart is imaged for pericardial effusion in this view, where dark fluid would appear adjacent to the heart.

Using FAST bladder views, verification of the presence of a urinary catheter can also be performed by visualizing the catheter itself or the water-filled balloon of the Foley catheter. A large volume in the bladder in an anuric patient indicates obstruction or malplacement of the urinary catheter. Though several authors have defined methods for calculating bladder volume, its variable geometry precludes easy approximation of volume. However, a practitioner can judge whether there is urine in the bladder despite efforts at diuresis or catheterization.

Solid echogenic structures in the distended abdomen suggest the abdomen is filled with a foreign mass (tumor), enlarged or swollen viscera, or a collection of a solidifying substance such as exudative ascites or clotting blood. Such findings should discourage needle drainage of a space in the evaluation of abdominal distention or intraabdominal hypertension, unless there is also a large volume of free fluid.

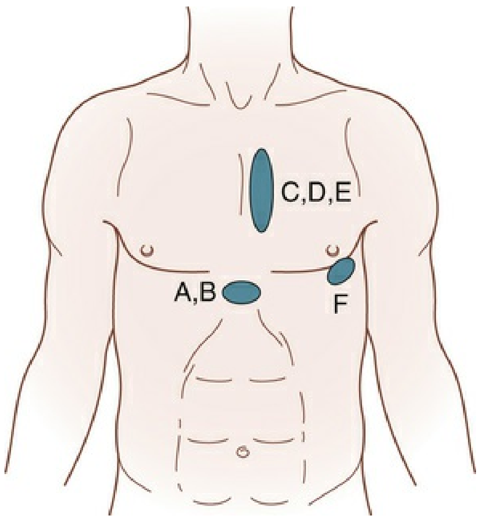
In shock management, some attention has been given to evaluation of renal perfusion as a surrogate for shock severity. A marked difference between systolic and diastolic renal arterial flow may suggest hypoperfusion.[60,61] However, to date examining this phenomenon has not consistently shown efficacy in evaluating shock states.[62-68] Whether this assessment will prove useful in children remains to be determined.

Cardiac Imaging

Imaging specialists often have a wide selection of phased array transducers for imaging the heart. Large adult-sized transducers, with more sophisticated technology and lower frequency transmission for adequate penetration, suit

adolescents and young adults well. Smaller transducers allow use of slightly higher frequencies for imaging infants and young children, and their smaller faces permit better skin contact when the probe is held at shallow angles to the skin. It is therefore important that adequate equipment be available for accurate bedside ultrasound cardiac evaluation of critically ill patients.

Imaging of the heart is performed using locations, or "windows," on the body where acoustic transmission to the heart is adequate and less encumbered by effects of body position and tissue interference. These include the subcostal window immediately below the xiphoid process, the parasternal window to the left of the patient's sternum, and the apical window near the patient's point of maximal cardiac impulse, typically below the left pectoralis major muscle. These windows form standard echocardiography views (Fig. 20.19).



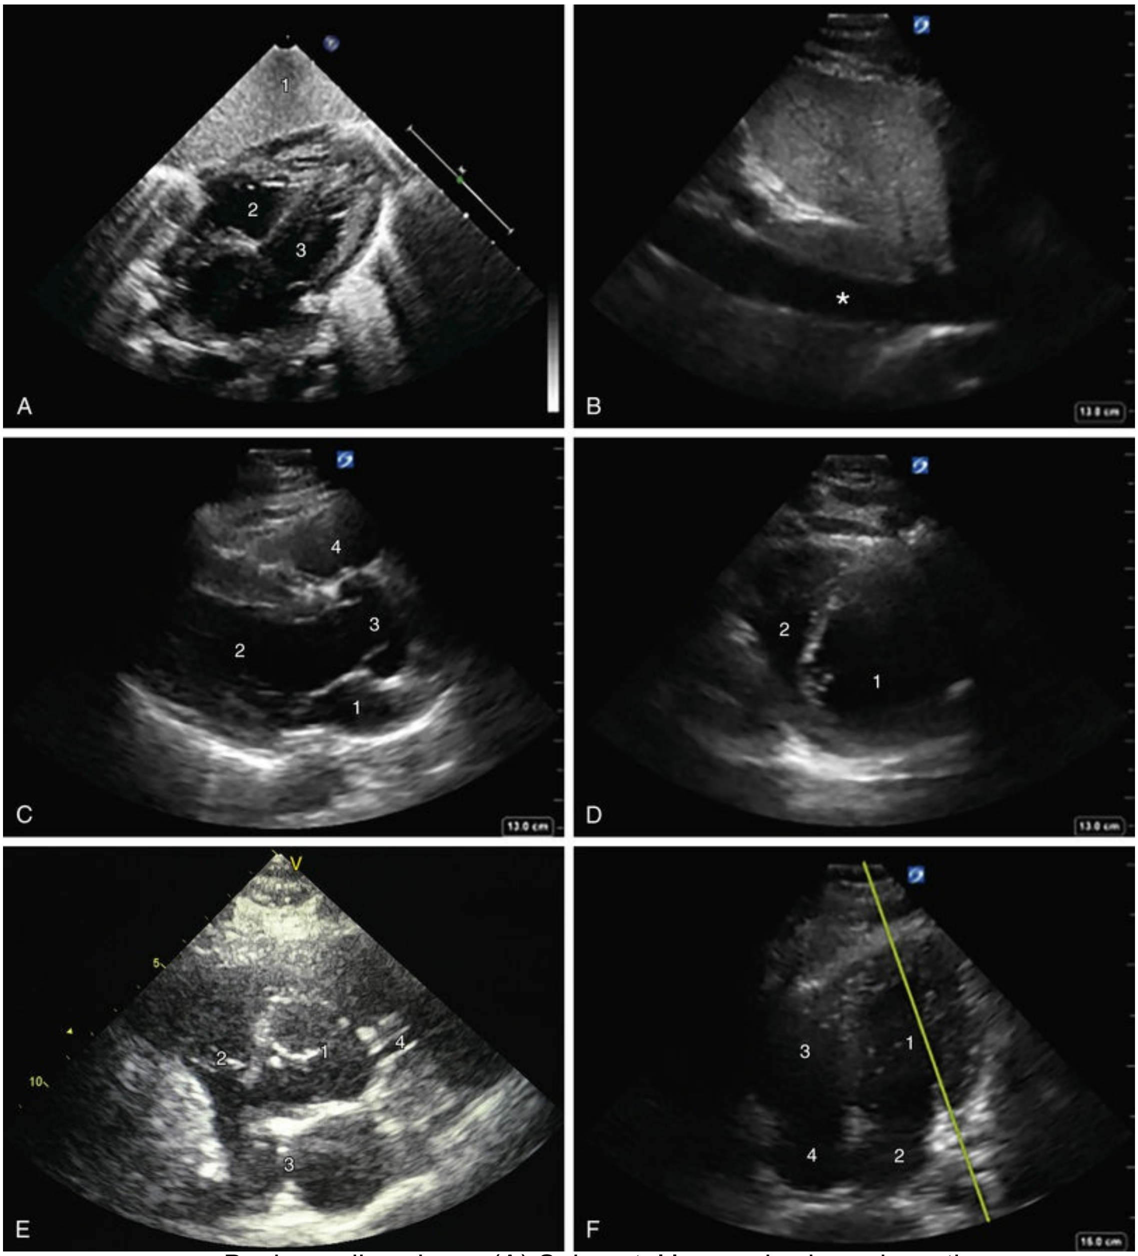


FIG. 20.19 Basic cardiac views. (A) Subcostal long axis view where the (1) liver, (2) right ventricle, and (3) left ventricle are visible. (B) IVC (*). (C) Parasternal long axis view where the (1) left atrium, (2) left ventricle, (3) aorta, and (4) right ventricular outflow tract are visible. (D) Parasternal short axis view at the midpapillary level where the (1) left ventricle and (2) right ventricle are visible. (E) Parasternal short axis at the aortic valve level where the (1) aortic valve, (2) tricuspid valve, (3) atrial septum, and (4) left coronary artery are visible. (F) Apical four-chamber view visualizing the (1) left ventricle, (2) left atrium, (3) right ventricle, and (4) right atrium.

Of note, different groups (ie, cardiology, emergency medicine, critical care medicine) may use different screen indicator orientations during cardiac ultrasound evaluation. Within the scope of this text, the screen indicator is at the top right of the screen for all cardiac views. Subcostal windows can be used to visualize the base of the heart either longitudinally, such that all four chambers are seen (Fig. 20.19A), or in cross section, such that only the atria or ventricles are seen. The probe is placed in

the subxiphoid region and beam aimed toward the patient's left shoulder. For a longitudinal view, the probe indicator is directed toward the patient's left flank, or approximately the 2 to 3 o'clock position with the top of the “clock” oriented toward the patient's head. For a transverse view, the probe indicator is directed at the patient's head and the view aligned across the chambers of interest. From the transverse view, the probe can also be directed directly posteriorly through the inferior vena cava (Fig. 20.19B) as it passes into the right atrium to assess its size variation through the respiratory cycle or through the aorta for evaluation of flow. Any view of the heart should be more than a single image, and fanning the transducer beam through the organ can provide the most complete impression of the heart. Septal defects are most easily visualized from the subcostal position using Doppler sonography because flow across them is most parallel to the ultrasound beam. In addition, the window is closest to the base of the heart and provides excellent imaging of effusion, particularly if the patient is slightly inclined head up. This window also has an advantage in small children with multiple dressings or monitoring devices on the chest because the subcostal window may be the only area not obscured.

Subcostal views are also important during active resuscitation from cardiac arrest when chest compressions must have priority. Ultrasound may reveal important information regarding the etiology of arrest including pericardial effusion, pulmonary embolism, and hypovolemia. Though subcostal windows benefit from not having intervening lung tissue obscure the heart, they can be hindered by interference from a gas-filled stomach and or bowel. In the case of internal interference from air-filled viscera, insonating the base of the heart from a position slightly overlying the right lobe of the liver can sometimes improve the view. Subcostal views may also be difficult in patients with substernal chest tubes or ventricular assist devices.

Views from the parasternal windows are commonly acquired from the third and fourth intercostal interspaces near the sternum on the patient's left chest. To acquire the parasternal long axis view (Fig. 20.19C), the transducer indicator is toward the patient's right shoulder and aligned along the major axis of the left heart. From this view the left atrium, mitral valve, the left ventricular chamber, and left ventricular outflow tract (LVOT) are readily visible in continuity with the right ventricular outflow tract that appears anterior to the LVOT. This view can be modified to image the right ventricular inflow view by fanning the transducer anteriorly through the right heart. The right atrium and IVC are usually visible and the tricuspid valve opens into the right ventricle anterior and caudad to the right atrium. The SVC may be visualized in infants though it is frequently obscured by the lung in an older patient.

The parasternal window can also be used for visualizing the heart in a plane perpendicular to its major axis, or the short axis view (Fig. 20.19D). Short axis views are performed with the transducer indicator aligned toward the patient's left shoulder. There are several short axis views that span the length of the heart from atrium to apex. Imaging the ventricle at the midchamber level is useful for the pediatric intensivist to assess qualitative left ventricular function, as this location is where radial contractility is most pronounced. In this view the beam transects the ventricle such that the papillary muscles are the primary intraventricular structures visible, with the inferoseptal papillary muscle appearing in the lower left and the

anterolateral papillary muscle appearing in the lower right of the image. A short axis view of the heart can also be performed at the aortic valve level. In this view the aortic leaflets are visible and roughly form a lambda sign in the middle of the appropriately centered image (Fig. 20.19E). With careful targeting the left or right coronary root is sometimes visible in this view. On the screen, the left atrium is directly posterior to the aortic valve (6 o'clock) and moving clockwise is the right atrium (8 o'clock), tricuspid valve (9 o'clock), right ventricle (12 o'clock), and pulmonary valve (2 o'clock) with the pulmonary artery and its bifurcation sometimes visualized at the 4 o'clock position.

Apical views (Fig. 20.19F) are very dependent on thoracic and abdominal structures. Increased intrathoracic pressure, as in asthma or high airway pressure ventilation, can cause the apex of the heart to move caudad and medially. Hyperinflated lung may obscure the apex. Conversely, high intraabdominal pressure can push the diaphragm cephalad and displace the heart cephalad and laterally. Apical views are insonated near the point of maximal impulse at the caudad aspect of the left pectoralis major muscle. The axis of the probe should be aligned with the major axis of the heart and point toward the center of the mediastinum. For the apical four-chamber view, the indicator is oriented toward the left flank, usually between the 2 and 3 o'clock positions. From this view the four chambers and both atrioventricular valves of the heart should be visible. In addition to the four chambers, this view allows visualization of both atrioventricular valves and their movement. The left heart appears on the right of the screen, and atria appear at the bottom when the probe face appears at the top of the screen. From the four-chamber view, the transducer can be fanned anteriorly so that the beam intercepts the LVOT for interrogation of outflow velocity. This is called the *apical five-chamber view.* From the four-chamber view, the probe can be rotated 60 degrees counterclockwise to obtain a two-chamber view of the left heart (left ventricle and atrium) for assessment of function.

Cardiac ultrasound can provide assistance in titrating fluid, inotropes, and vasopressors for persistent shock in children.[69,70] Initial pediatric experience has demonstrated that its use is feasible and associated with good outcome, complementing available adult data describing the utility of intensivist-driven cardiac ultrasound for hemodynamic assessment. It is reasonable to surmise that the value of focused cardiac ultrasound noted in adults[71] might be similar or better in children, as views of the heart may be better given pediatric body habitus.

Most literature related to cardiac ultrasound for hemodynamic assessment in children has focused on volume status assessment. Adult echocardiographers and pediatric nephrologists have used the collapsibility and distensibility of the compliant inferior vena cava as a noninvasive surrogate for volume status and estimation of dry weight for dialysis patients, respectively.[72,73] Beyond volume, IVC morphologic changes may also represent variable upstream pressures, and estimates of central venous pressure based on IVC imaging data have been published for adults.[74]

The diameter of the IVC is usually assessed in the sagittal view about 2 to 3 cm caudad to the inferior cavoatrial junction in adults. At this point the vessel diameter can be measured using M-mode or two-dimensional (2D) methods. Available evidence regarding IVC assessment for volume status is largely related to two physiologic conditions: (1) the patient who is pharmacologically paralyzed and

intubated receiving a set tidal volume at near normal airway pressure and (2) the spontaneously breathing patient. IVC respiratory variation exceeding 12% to 18% in the neuromuscularly blocked adult patient[75,76] has been described as a threshold for volume responsiveness. Current convention in the adult is the use of maximum diameter observing for changes greater than 12%. Similar criteria have not yet been established in children. The degree to which airway pressure decreases respiratory variation and masks hypovolemia by increasing intrathoracic pressure is also not well delineated. Increasingly evidence, specifically in children, indicates that IVC behavior is not equivalent in the two respiratory conditions. In the pediatric operating room, titration of positive pressure ventilation as well as initiation of inhalational anesthesia changes the collapsibility of the IVC.[77] Increasingly evidence indicates that IVC behavior is not equivalent between patients receiving sedation and positive pressure ventilation compared to those spontaneously breathing.

Using a ratio of the size of the inferior vena cava to aorta diameter IVC:Ao in a transverse view may provide a useful assessment of volume status in children and avoids the challenge that results from the range of sizes in children. An IVC : Ao ratio of 0.8 or less appears to suggest clinically significant dehydration, whereas a ratio greater than 1.2 : 1 suggests hypervolemia.[72] Fluid responsiveness was not described, however; this study targeted diagnosis rather than evaluation of physiologic response to therapy. However, in critically ill children, limited data suggest that IVC : Ao and IVC collapsibility are poor surrogates for central venous pressure.[78] In addition, despite its use in septic shock algorithms as a surrogate marker for intravascular volume depletion, central venous pressure (CVP) measurements have come under considerable scrutiny given their poor accuracy.[79] Intensivists are only beginning to understand the complex interactions between pressure, volume, and compliance on IVC morphology in individual patients undergoing life-sustaining therapies in states of critical illness.

Assessment of left heart performance as a surrogate for volume status has also been an area of interest in adults and children. Velocity of blood flow across LVOT has been used as a surrogate of stroke volume and indicator of intravascular volume status. Assessment of the left ventricular outflow tract using Doppler ultrasound is performed from the apical five-chamber view observing velocity of left ventricular ejection (Fig. 20.20). Stroke volume can be approximated by obtaining the Doppler velocity tracing of flow across the LVOT over time, calculating its integral (VTi), and multiplying this by the measured cross-sectional area of the LVOT. The cross section of the LVOT is usually measured from the parasternal long axis view using the diameter measured between the aortic valve leaflets in midsystole.

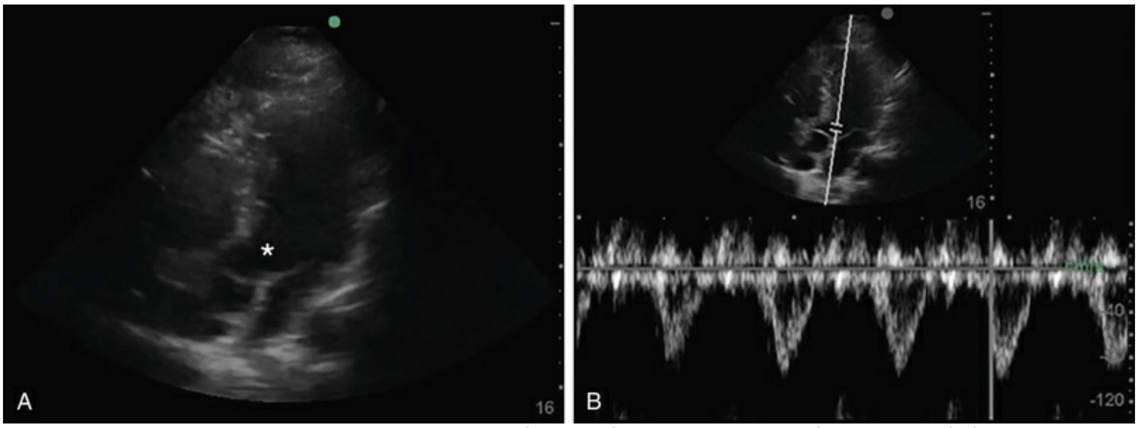

FIG. 20.20 Doppler interrogation of the left ventricular outflow tract. (A) Apical five-chamber view with (*) LVOT identified. (B) Pulsed wave Doppler of the LVOT.

Using the estimated stroke volume and multiplying by the heart rate allows approximation of cardiac output. The LVOT Doppler tracing can also provide a beat-to-beat assessment of changes in stroke volume through the respiratory cycle. Respiratory changes in peak LVOT velocity exceeding 14% appear to identify volume responsiveness in intubated pediatric intensive care unit (PICU) patients.[80,81] In assessing variability in the Doppler flow tracing it is advisable to slow the sweep speed of the machine so multiple systolic ejection events are observed through the respiratory cycle. Variability of 14% is thought to indicate volume responsiveness. Pitfalls of this technique include limited apical views due to lung inflation and patient habitus. Further concerns particular to pediatric patients include the need for a smaller phased array transducer to maintain skin contact and small LVOT for appropriate placement of the Doppler cursor, made more challenging in the dehydrated child with a hyperkinetic heart.

Effusion in the pericardial space appears similar to pleural effusion as a largely dark and anechoic space separating the heart from the reflective pericardium (Fig. 20.21). Effusion may not be concentric and instead collect in dependent areas; therefore subcostal windows are often ideal for visualizing them. Effusions can also be complex as a result of accumulated protein in an empyema, solidification of hemorrhage, or presence of tumor.

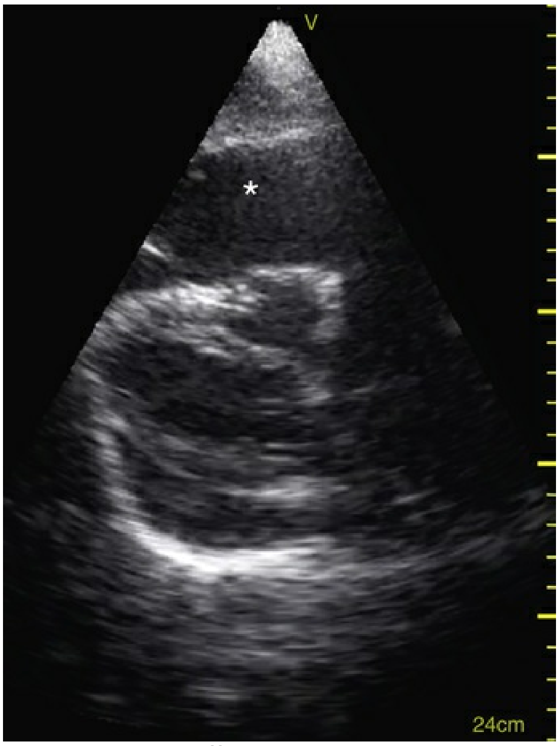

FIG. 20.21 Pericardial effusion. *Asterisk* indicates effusion.

Tamponade is a clinical diagnosis; however, the presence of an effusion and subsequent changes to cardiac morphology and function suggestive of tamponade physiology are detectable using ultrasound. The most specific indicator of tamponade is IVC engorgement secondary to impeded venous return to the heart. Other ultrasound findings consistent with tamponade may include collapse of the low-pressure right heart chambers during filling periods in the cardiac cycle, namely late diastole/early systole in the right atrium and early diastole in the right ventricle.[82] Respiratory variation in the left ventricular inflow is also associated with tamponade physiology as demonstrated by noticeably reduced mitral inflow during inspiration. Conversely, inflow across the tricuspid valve may increase during inspiration.

Pericardiocentesis

Concomitant imaging often facilitates pericardial effusion drainage. Use of a phased array probe in the apical position may not allow visualization of the needle but permits monitoring effective drainage of the effusion and wire placement for drain placement. Injecting a small quantity of agitated saline into the pericardiocentesis needle for sonographic contrast can help confirm that a needle is in the pericardial space rather than a vascular space, particularly if an effusion is bloody.[83] A dynamic visualization technique described for pericardiocentesis in adults uses a linear array transducer placed in the left parasternal area with the indicator pointed cephalad.[84] This technique allows visualization of an effusion anterior to the heart and an insertion site identified that avoids the internal mammary artery. A needle can then be inserted under long axis guidance, avoiding the artery from the caudad side of the probe toward the head, and drainage performed under direct needle guidance. Whether this has broad applicability in the pediatric setting remains undetermined.

Left Ventricular Cardiac Function

Although the best metric for characterizing cardiac contractility remains elusive, acute care practitioners can estimate cardiac function using qualitative and quantitative markers with reasonable accuracy when compared to echocardiography specialists.[85,86] The motion of the left ventricle (LV) assessed through the cardiac cycle is useful for this assessment. Visualizing the LV across the center of the chamber in multiple views, a sonographer can visually approximate or directly measure the excursion of the ventricular walls. These values are then compared to known standards (eg, a normal left ventricular fractional shortening [FS] measures between 25% to 45% of the LV end-diastolic diameter). This measurement is optimally performed quantitatively in the parasternal short axis view at the midpapillary level.

Area-based measurements of LV systolic function are also useful. These include changes in the cross section of the LV seen in the short axis or apical views (ejection fraction [EF]) by Simpson's method of discs. Area-based calculations are advantageous to single dimension assessments such as FS because they reduce the effects of regional wall motion abnormalities on accuracy of EF measurement. These calculations are prone to error from inaccurate inclusion of intracavitary structures such as the papillary muscles and trabeculae, as well as various artifacts. Apical views are also challenging in a child without appropriately sized transducers or if the lungs are hyperinflated, and this can compromise accurate assessment of the left ventricle EF. Substantial mentored practice is strongly recommended for skill development and accurate results.

M-mode modalities such as E-point septal separation (EPSS) and mitral valve annulus plane of systolic excursion (MAPSE) can also approximate systolic function. EPSS assesses the relative motion of the mitral valve anterior leaflet during diastole (Fig. 20.22). In the parasternal long axis view, at early diastole the leaflet is readily visualized as being more proximal to the probe and moving toward the septum both in the early passive phase of ventricular filling and late phase with atrial contraction. In the failing heart, end-systolic volume increases and diminishes the gradient across the mitral valve for flow into the LV during diastole. The excursion of the anterior mitral valve leaflet is therefore less pronounced and does not come as close to the septum. The distance between the leaflet and the septum is measured in the parasternal long axis view by placing the M-mode cursor across the mitral valve (MV) tips of the leaflets. In the adult, a normal EPSS is less than 6 mm and an abnormal one exceeds 10 mm. Normal values have been published in pediatric populations.[87,88]

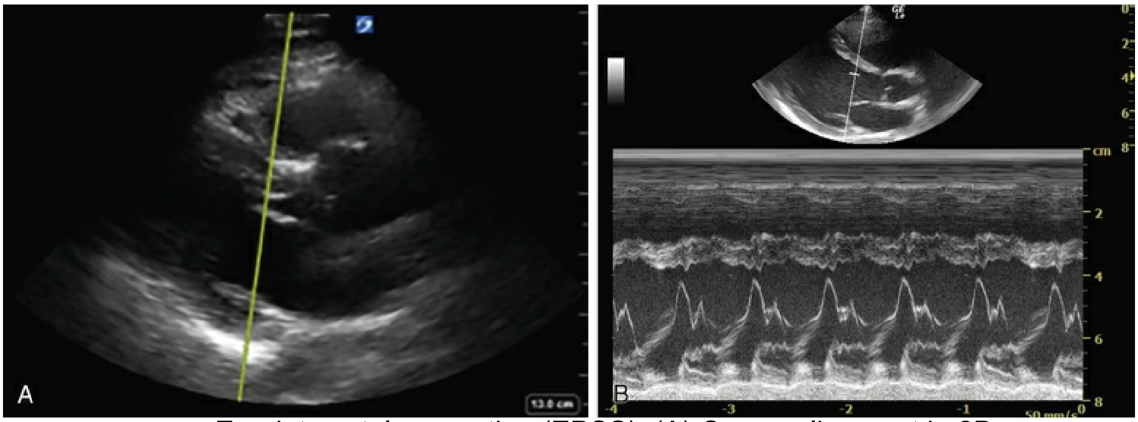

FIG. 20.22 E-point septal separation (EPSS). (A) Cursor alignment in 2D imaging for (B) M-mode measurement of EPSS.

MAPSE is assessed from the apical view of the MV by placing the M-mode cursor across the lateral end of the MV annulus (Fig. 20.23). In M-mode the vertical excursion of the MV apparatus is quantified as an approximation of the longitudinal contraction of the heart. The septal end of the MV can also be measured, though this tends to be a better indicator of biventricular function. Normal values have been published for pediatric populations.[89]

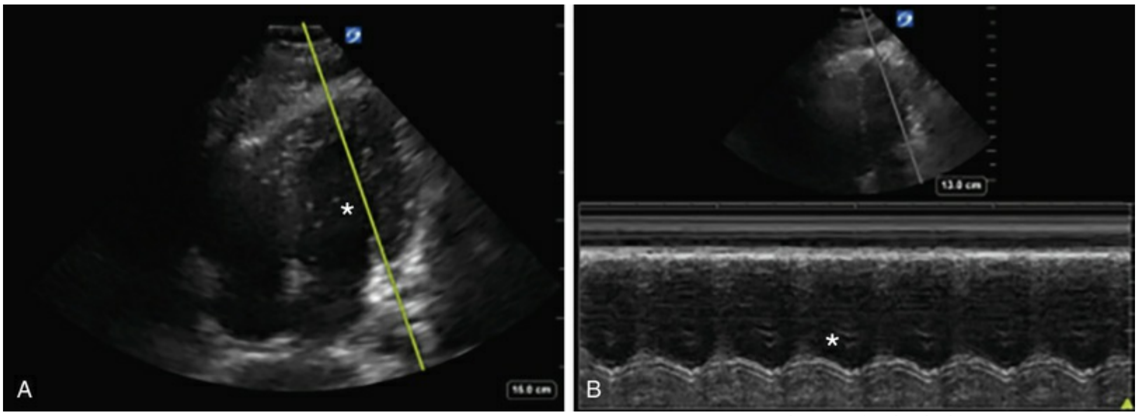

FIG. 20.23 Mitral annulus plane of systolic excursion (MAPSE). (A) Cursor alignment in 2D imaging for (B) M-mode measurement of MAPSE. Vertical excursion of the lateral side of the mitral valve annulus *(asterisk)* is measured to determine MAPSE.

Right Ventricular Cardiac Function

In the PICU, assessment of the right ventricle (RV) can provide valuable information about the effects of pulmonary vascular resistance changes and mechanical ventilation on cardiac performance. Assessment of the RV can, however, be difficult because of its position closer to the sternum and its triangular shape straddling the left ventricle and making characterization of its movement through the cardiac cycle difficult. Subtle signs of RV dysfunction can be seen with dilation and pulsatility in the inferior vena cava, although some pulsatility can be normal in both the IVC and subclavian veins. From the apical position or parasternal right ventricular inflow or parasternal short axis view at the aortic valve level, identification of a tricuspid valve

regurgitant jet can potentially be used to evaluate RV systolic pressures. Quantification of jet peak velocity permits derivation of the pressure gradient between the right ventricle and atrium using the modified Bernoulli equation, where $\Delta P = 4(v_2 - v_1)^2$ with v_1 representing velocity of blood flow distal to the tricuspid valve and v_2 representing velocity of flow in the jet. This simplifies to $\Delta P = 4{v_2}^2$ given v_1 approximates zero in systole. Body habitus and pulmonary inflation may make identification of a tricuspid regurgitation (TR) jet difficult in ICU patients,[90] and less severe RV dysfunction may not generate a jet.

Other clues to RV dysfunction include leftward interventricular septal deviation. Septal deviation can be visualized in multiple views; however, it is most prominent and appropriately evaluated in the parasternal short axis view at the midpapillary level. Septal position can reveal right ventricular volume overload from pressure overload as a cause of RV dysfunction (Fig. 20.24). Volume overload is typically characterized by septal deviation occurring in diastole but not systole, resulting in the left ventricle assuming a predominantly circular conformation during systole. In the progression of RV failure to pressure overload of the ventricle, septal deviation is seen through the entire cardiac cycle.

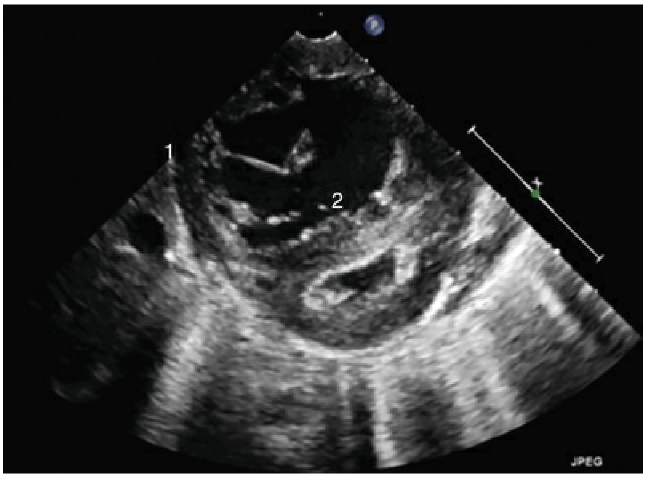

FIG. 20.24 Chronic severe right ventricular failure. Note thickened (1) right ventricular wall and (2) interventricular septum that bows into the left ventricle.

Cardiac Arrest

During cardiac arrest, ultrasound may help immediately identify reversible causes of arrest, including critical hypovolemia and pericardial effusion with tamponade physiology.[38] In the modern PICU, ultrasound machines are easily deployed to the arresting patient's bedside for patient management. However, their use in cardiac arrest requires particular attention to patient and provider. Ultrasound gel conducts electricity and must be wiped from the skin between ultrasound views in the event defibrillation is necessary. The gel makes contact surfaces slippery for clinicians providing compressions and may dislodge pads and monitoring. Timing is also critical, and coordination of a sonographer's view of the heart should be performed briefly during pulse checks to minimize interference with chest compressions. The

sonographer should not be the code team leader, so that sonography does not interfere with efficient CPR. Absent cardiac contractility, termed *cardiac standstill*, has been described as highly indicative of unlikely return of spontaneous circulation[91-93] in adults. In the pediatric setting, recovery of cardiac function after standstill has been described.[94] Placing the transducer in the subcostal position minimizes interference with compressors and defibrillator pads on the chest. Apical windows may also be possible but are often more difficult to acquire than subcostal windows, thereby consuming time in assessing for reversible causes of arrest.

Neurosonology

Distention of the optic nerve sheath demonstrated via direct ophthalmic ultrasound can potentially provide evidence of increased intracranial pressure.[95] The eye is imaged from the front over the closed eyelid to visualize the sheath approximately 3 mm behind the vitreous humor and retina. Careful measurement of the maximum sheath diameter is important to decrease the risk of underestimating pressure. Copious gel, preferably made for ophthalmic use, is advised to reduce eye irritation. There are limited data about normal or abnormal values for children of different ages or different intracranial disorders. A similar view surveying the posterior retinal space has also been described in examining retinal pathology for retinal hemorrhages in child abuse and has also been employed in examining traumatic and infectious pathologies involving the eye.[96] The diagnostic utility of this application remains under investigation.

Use of transcranial Doppler for assessing cerebral blood flow has become common for monitoring vasospasm in patients with subarachnoid hemorrhage and other disorders encountered in the adult neurocritical care unit. There is considerable interest in its application in pediatric neurocritical care as a noninvasive assessment tool for cerebral perfusion. Insonating the middle cerebral artery from the temporal window lateral to either eye requires a low-frequency transducer that can operate near 1 MHz. It is also possible to insonate the anterior cerebral artery in patients with an open anterior fontanelle, and the vertebrobasilar system can be insonated from the foramen magnum with some occipital support and care not to disrupt a critical airway or cervical spine. Color Doppler is used to image the cranial vessels, and pulsed wave Doppler can subsequently be employed to identify velocities in the vessel of interest. From the peak systolic (SBF) and diastolic flow (DBF), the resistive index can be calculated as RI = (SBF-DBF)/SBF or the pulsatility index as PI = (SBF-DBF)/(time-averaged mean velocity). An increasing RI or PI is suggestive of vascular constriction and a greater difference between systolic and diastolic flow.

Conclusion

Ultrasound technology is increasingly common in critical care medicine for procedural guidance and timely clinical assessment at the bedside. Optimal use requires an infrastructure to assure adequate training, but the dividends may have a powerful impact, including increased procedural safety, improved understanding of patient physiology, decreased time to diagnosis, and improved patient outcomes. More research is needed to determine ultrasound's role in the ICU, but with its ongoing incorporation into daily workflow new indications for its use are likely.

CHAPTER 21

Pediatric Critical Care in Resource-Poor Settings

Amélie von Saint, André-von Arnim, Niranjan (Tex) Kissoon

PEARLS

- Global child mortality is declining due to decreasing poverty and increasing quality and access to basic medical care.
- Given the large burden and high mortality of critical illness and availability of low-cost therapies, there is ample rationale for expanding critical care services in least-developed countries.
- Basic critical care interventions can be successfully provided in resource-poor settings without an ICU.
- Publicly funded ICU care remains limited in low-income countries, and its introduction requires careful resource allocation.
- Health care systems improvements for the critically ill should involve a graded approach of strengthening capacity to provide health maintenance, basic critical care, and then publicly funded intensive care services as overall health indices improve.
- Critical care research from low-income countries is sorely needed to guide effective and efficient care and advocate for resources.

Life-threatening illnesses are a global phenomenon with markedly disparate outcomes depending on available resources. The term "resource-poor setting" defines a locale in developing or underdeveloped countries where mortality is high, and the capability to provide critical care for life-threatening illness is limited. In rich, industrialized countries, caring for critically ill patients involves a coordinated system of triage, transport networks, and emergency and intensive care provided in well-resourced units. This cohesive service is resource intensive and hence not affordable for many low-income countries where care is fragmented. Indeed, the burden of critical illness remains inordinately high in low-income countries,[1] despite an overall recent decrease in global childhood mortality. Thus care of the critically ill with sudden, serious reversible disease should be a universal goal. While the systems available in resource-rich areas cannot and should not be the near-term goal,

a graded approach that involves strengthening capacity to provide health maintenance and implementing basic critical care followed by publicly funded intensive care services as overall health indices improve is a reasonable solution.

Child Mortality Rates

Current Trends and Health Maintenance

Globally, the under-5 mortality rate has decreased by nearly half (49%) since 1990, decreasing from 90 to 46 deaths per 1000 live births in 2013. This translates into 17,000 fewer children dying every day now compared with 1990 and a decrease in the contribution of deaths and disability of children younger than 5 years of age to the global disability-adjusted life years (adult and pediatric) from 41% to 25% between 1990 and 2010.[2] These gains may be partly attributed to attention to the Millennium Development Goals (MDGs), especially MDG numbers 4 and 5, which related to decreasing under-5 mortality by two-thirds and "improving maternal health" by reducing maternal mortality by three-quarters by 2015 from 1990 baseline.[3] These successes are due to decreasing poverty, increasing vaccination rates, access to medical care, improving quality of care, and other factors.

The under-5 mortality is currently falling faster than at any other time during the past 2 decades, but about 17,000 children younger than the age of 5 still die every day, with 6.3 million deaths annually.[4] In addition, gains have been patchy and the region with the world's highest under-5-mortality rates remains sub-Saharan Africa with roughly half (49.6%, 3.113 million) of those deaths. On average, 1 out of every 11 children born in sub-Saharan Africa dies before age 5. This is nearly 15 times the average rate in high-income countries.[4] The world's "bottom billion" living in poverty remains high even in rapidly emerging economies, such as India and China[5]: The five countries with the highest number of under-5 deaths in 2013 were India, China, Pakistan, Nigeria, and the Democratic Republic of the Congo.[6] Even if present trends in mortality continue, 4.4 million children younger than 5 years will die in 2030.[6] Thus despite substantial gains there are still great and burgeoning needs for critical care for children globally (Fig. 21.1).

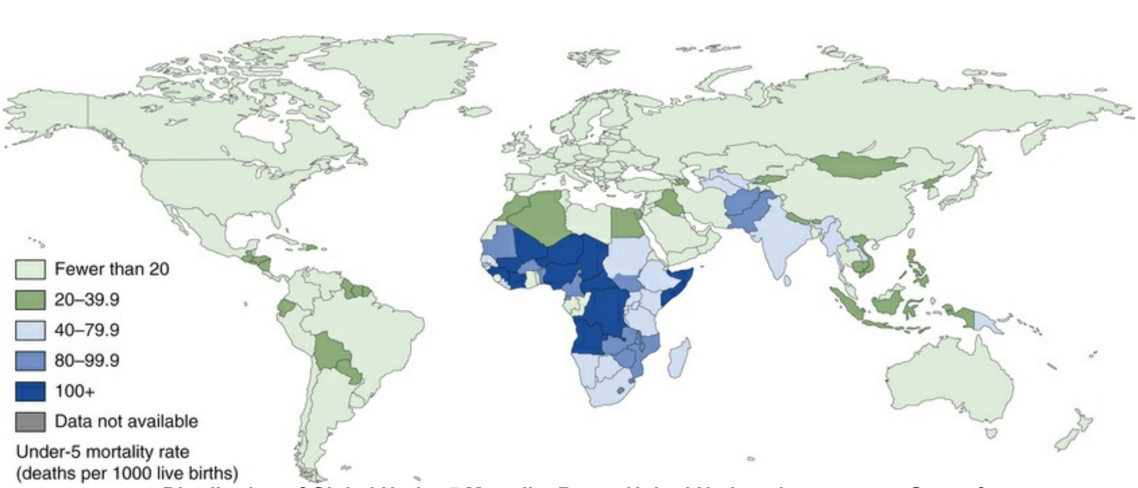

FIG. 21.1 Distribution of Global Under-5 Mortality Rates. United Nations Inter-agency Group for Child Mortality Estimation (IGME). (From UNICEF: Committing to child survival: A promise renewed progress report 2014, UNICEF, New York 2014. Available at: http://data.unicef.org/child-mortality/under-five#sthash.SSSCDvl3.dpuf.)

Justification for Critical Care

Of the 6.3 million children who died in their first 5 years of life in 2013, 52% died of infectious causes.[6] Pneumonia, diarrheal diseases, and malaria were the leading infectious causes: pneumonia caused 0.935 million, diarrhea 0.578 million, and malaria 0.456 million deaths.[6] While substantial gains have been made in under-5 mortality, gains in neonates have been small with neonatal deaths contributing 44% of under-5 deaths. Other important causes were injury, which contributed to 0.324 million deaths,[6] with overall 90% of global trauma deaths occurring in low- or middle-income countries.[7] Thus infectious diseases remain the leading cause for child mortality. Half of the infectious disease–related under-5 deaths are associated with malnutrition, mainly among the poor in low-income countries (Fig. 21.2).[3]

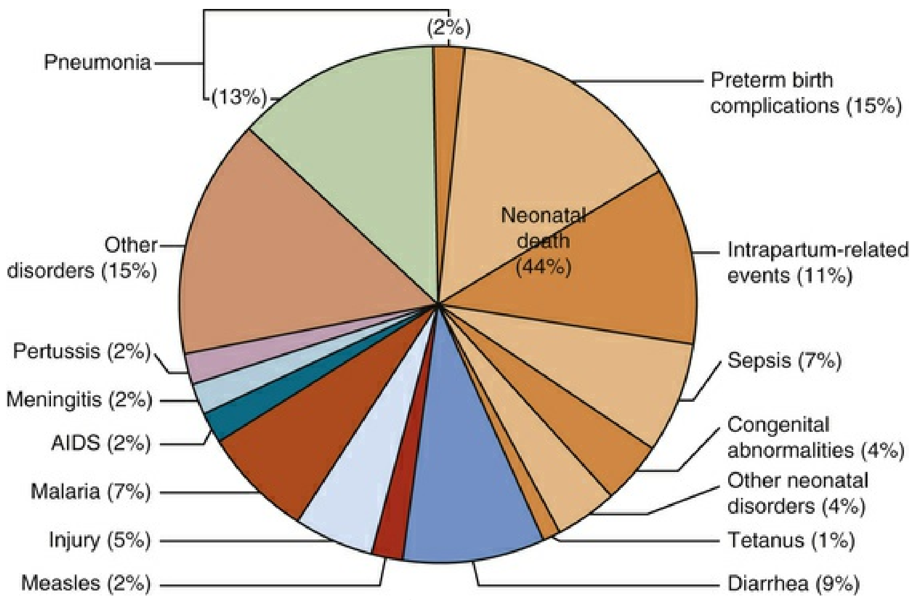

FIG. 21.2 Estimated number of deaths by cause in 2013. (From Liu L, et al. Global, regional, and national causes of child mortality in 2000-13, with projections to inform post-2015 priorities: an updated systematic analysis. Lancet. 2015;385:430-440.)

The number of deaths is clearly an underestimate because methods of measuring health outcomes are limited in middle- and low-income countries. For instance, in sub-Saharan Africa, only South Africa captures more than 50% of deaths in a vital registration system. The lack of death registries renders it difficult to estimate the burden of critical illness and hence limits the ability to hold governments accountable for their organization of health systems.[8,9]

The three general approaches that have been suggested to try to estimate global burden of critical illness have significant limitations.[10] These include the following: (1) counting patients admitted to ICUs around the world; (2) extrapolating from resource-rich countries' epidemiology; and (3) using the assumption that all deaths occurring in a region had a critical illness at some stage before their demise. The first two approaches will likely lead to an underestimation, and the third will lead to an overestimation of the burden of critical illness in resource-poor settings. However, by all indications the burden is enormous and likely to rise with increasing

urbanization and epidemics.[1,11-13] Access to medical care may improve outcome but will increase the demand for critical care.

Given the high burden of critical illness in least-developed countries with a collective population of greater than 366 million children and adolescents,[14] the associated high mortality, and availability of low-cost strategies for the management of many critical illnesses, there is ample rationale for expanding critical care services in these regions of the world.

Critical Care in Resource-Poor Settings

Critical care can be defined by the severity of illness, complexity of the care that is offered, and training of the professionals who provide that care.[15] For the purposes of this chapter, however, we define pediatric *critical care* as the care of children who suffer a life-threatening illness or injury regardless of the location where care is provided. As an example, critical care includes treatment for severe pneumonia, malaria, or diarrheal diseases at district clinics and health centers, as well as tertiary-care hospitals. Thus critical care can be provided from the time of first presentation to the point of discharge home.[16] In contrast, we define *intensive care* as care provided for the critically ill or injured or those who have undergone major surgical procedures in an ICU. These units vary in resources (personnel, equipment, and supplies) and hence the level of care that can be provided but share the common characteristic of being a designated area in a hospital. Thus delivery of critical care services is not specific to a site and could be provided in the prehospital setting, emergency department, hospital wards, or intensive care unit.

In high-income countries, critical care services usually involve "a coordinated system of triage, emergency management, and ICUs" providing contemporary standards of care to the population.[17] Some urban university and private hospitals in sub-Saharan Africa, India, and China may offer critical and intensive care services close to high-income countries, but in many low- to middle-income countries (LMICs), health care systems are poorly organized, human and material resources are scant, and intensive care services are few or nonexistent, especially at the hubs of medical care, the district-level hospitals.[18-23] In sub-Saharan Africa, inadequate delivery of evidence-based, essential interventions continues to be a major obstacle.[24,25] Even quality of care for common childhood illnesses such as pneumonia and diarrheal diseases is poor in these settings.[20,26] Logistic and financial limitations, poorly resourced supporting disciplines (eg, laboratories, radiology, nursing), poor general health status of patients, underlying malnutrition, delayed presentation of severely sick children, and suboptimal care contribute to comparatively high mortality. As an example, a recent survey of Kenyan government hospitals revealed a median availability of essential antibiotics in only 36% of the 22 surveyed facilities, with a wide range of essential resource availability from 49% to 93%.[27]

Intensive Care in Resource-Poor Settings

Where ICUs are available, the most common reasons for admission are for postsurgical and trauma care, infectious diseases, and peripartum maternal or neonatal complications.[28] These conditions are major contributors to the global burden of disease. Hence, building critical care capacity around the relevant

disciplines (eg, surgery, obstetrics, pediatrics, internal medicine) where they already exist is a reasonable method to increase capacity. Increasing capacity may also entail providing more personnel, equipment, and supplies. For instance, an ICU in a public hospital often provides pressurized air or oxygen, but mechanical ventilation or renal replacement therapy is limited.[18] What may be found in a district-level hospital in sub-Saharan Africa is a four- to eight-bed ICU with one or two nurses. Fifty percent of the patients may have an empty IV drip and no patient monitors, mechanical ventilators, necessary disposable materials, or electricity. Oxygen is an expensive resource and not always available because of difficulties in refilling cylinders, and reliable electricity to power oxygen concentrators generally does not exist.[18]

Basic Critical Care in Resource-Poor Settings

Critically ill children in LMICs may benefit from timely care even without an ICU. Innovative and successful basic critical care interventions in these settings are increasingly evident. These include the training of villagers in basic first aid and resuscitation[29]; provision of low-cost simplified antimicrobial regimens and rapid diagnostic tests to rural health care workers, day clinics, and homes[30-32,33]; quality improvement of district hospital services[34,35]; reorganization of emergency services at referral hospitals[36,37]; provision of oxygen therapy for hypoxemic children with pneumonia in district clinics; and medical treatment given by village workers or parents,[38,39] which all have proven to be effective and beneficial to critically ill children. Great gains have been made in treating pneumonia by the introduction of oxygen concentrators, oximetry monitoring, and supplemental oxygen administration in Papua New Guinea. These interventions decreased pediatric pneumonia case fatality by 35% at very low cost.[40] Noninvasive respiratory support such as Bubble-CPAP has been successfully and cost-effectively introduced for support of neonates and infants with respiratory compromise in limited-resource settings.[41-46] Use of simple nurse-initiated CPAP protocols for children up to 5 years of age has been successfully and safely introduced to some rural hospitals in Ghana.[47] Devices delivering CPAP or BiPAP can reduce the work of breathing and improve functional residual capacity, potentially avoiding intubation and preventing harm and high costs related to invasive mechanical ventilation.[48,49]

Cost of Intensive Care

Intensive care involving ICUs and mechanical ventilation is expensive, as opposed to the much lower-cost basic critical care interventions described earlier. The cost of intensive care includes expenditures for increased personnel, equipment, consumables, and expenses associated with potential long-term morbidity of survivors. The high fixed costs of ICU care contribute significantly to the limitations of an ICU infrastructure in low-resource settings.[9] Differing health insurance schemes and socioeconomic divisions can introduce significant variations in how patients are treated, both in terms of likelihood of admission to the ICU and care in the ICU.[50] The evidence indicates that universal health care coverage schemes in LMICs improve access and utilization of basic medical services,[51] which may positively affect ICU care going forward.

Defining the capacity to deliver intensive care in LMICs is challenging given the absence of uniform definitions of an ICU bed.[52,53] More than 50% of low-income countries lack any published data on ICU capacity.[53] In a recent review, the only countries with national ICU bed data, Nepal and Uganda, had 16.7 and 1.0 ICU beds per million people, respectively.[53] In a national survey in Zambia, only 7% of 68 hospitals surveyed offered ICU care, translating to 29 ICU beds for a population of 11.7 million.[54] Most ICUs in these settings are located in referral centers or university hospitals of large cities.[53,54] However, the presence of an ICU bed does not imply the ability to effectively care for critically ill patients.[55] Moreover, the data presented represent predominantly adult ICU beds that may accept a child on rare occasions. Even when children are admitted, age-appropriate equipment and supplies and care providers with pediatric experience are rarely available.

So one may ask, "Is increased intensive care infrastructure in limited-resource settings worthwhile?" The World Health Organization defines a "very cost-effective" intervention as one that costs less than the value of gross domestic product (GDP) per capita per disability-adjusted life year.[56] This includes many primary care and preventative interventions[57,58] and some surgical interventions.[59-62] ICUs in high-income countries function in large part by admitting and caring for complex patients with often incurable diseases,[63] whereas in many resource-limited settings, the ICU provides basic rescue interventions for children and young adults who are ill with curable diseases. Although provision of intensive care services may not seem rational or cost-effective in low-income countries, a short duration of critical care that is cost-effective and treats acute life-threatening illnesses affecting millions of young people worldwide may have a large impact on mortality from curable disease and reduce preventable deaths.[63] It is suggested that publicly funded expensive intensive care is justified in countries with under-5 mortality rates of less than 20 to 30 per 1000 live births. However, in settings where under-5 mortality rates are greater than 30 per live births, focus on basic critical care interventions specified earlier is more appropriate.[15,64] Research into cost-effective interventions in the setting of curable diseases is needed to further understand which critical care interventions are appropriate and sustainable, as well as how best to allocate resources.

Ethics of Intensive Care in Resource-Poor Settings

Development of publicly funded intensive care services in resource-poor settings raises many challenges. According to the global justice argument, health care services are a fundamental and universal human right available to everyone.[10] The *just* distribution of health care services across all human populations remains a serious challenge. Global justice would imply that those in resource-rich regions have a responsibility to combat critical illness and strengthen health care infrastructure for those in resource-poor settings.[65] In countries with per-capita health care investments less than $100 per person per year, the cost of intensive care renders its provision for everyone impractical. To attempt to provide access to ICUs at the standard of care accepted generally in the developed world will lead to serious distortion of health care budgets and have detrimental effects on overall health of the

nation. Alternatively, access to different standards of care or differences in quality and breadth of critical care will develop or already has developed in LMICs. In such an inegalitarian health care policy, which is common in many developing nations, "centers of excellence can be maintained where critical care technologies can be nurtured so that as a country develops and increases its standards of care, it will have its home-grown critical care resources on which to draw."[66] Such centers can harbor the skilled personnel within a country who can serve as catalysts in expanding high-quality care as economic resources increase and mortality gains are realized. In these systems, the key lies in extreme efficiency measures and meticulous attention to balancing the needs of individuals versus those of the population. Lessons learned from innovative methods in delivering critical care in less than ideal conditions and with fewer resources can lead to reverse innovations and be beneficial to both resource-rich and resource-poor worlds.

Providing ICU-level care also requires respecting family, cultural, and religious preferences. Different practices are present in different countries with respect to whom is accepted as the appropriate decision maker on initiation or discontinuance of critical care services. In particular, such decisions are often made by the family rather than patient.[66] In many African countries the idea of advanced directives and code status have yet to be discussed at the national judicial and medical community level.[67]

Resource allocation of intensive care services in deprived areas of the world is challenging and should be defined for each institution. As an example, the Red Cross War Memorial Hospital in South Africa published explicit patient exclusion criteria for offering critical care, in an attempt to provide a reasonable process for fair and equitable utilization of scarce resources.[68] Some of these exclusion criteria are futile care for children declared brain dead or status post cardiac arrest without establishment of normal respiratory pattern; children with underlying lethal conditions, such as children with burns on more than 60% of their body surface area with limited ability to provide timely surgical debridement; children with chronic renal failure with no ability to commit to long-term dialysis; children with severe/lethal chromosomal anomalies; and children with malignancies nonresponsive to therapy or inoperable cardiac lesions. Although this is a reasonable approach, implementation should be undertaken with great sensitivity to both the family and staff or it is likely to lead to failure, anger, and cynicism. In addition, careful decisions regarding the extent of ICU support need to be made in the context of potential impoverishment of the entire extended family, especially if the end result is a child's death or long-term morbidity.

Suggested ways to address ethical dilemmas of resource allocation in resource-poor settings include the following: obtaining data on disease prognosis with and without ICU care to inform clinical decision making; development of procedures for addressing level-of-care decisions openly and honestly; and articulating hospital policies on the use of critical care services, including policies regarding appropriate ICU admissions, cardiopulmonary resuscitation, and ventilator candidates.[67]

Strengthening Critical Care Infrastructure

Health Care Systems

There is no one blueprint for an ideal health care system, nor is there a remedy that will automatically elicit improved performance.[69] Building critical care services in LMICs requires a tiered approach, starting by improving delivery of evidence-based, basic, essential health care interventions, especially for countries with under-5 mortality rates greater than 30 per live births.[64,70,71] This requires broad strengthening of national health systems because a multitude of factors may influence how services are actually delivered, including financing, human resources, governance, and information systems, in addition to more traditional concerns over knowledge, skills, and availability of technologies.[72,73] A focus on district-level hospitals seems ideal because they are typically linked to a network of primary care and community-based health services and are more accessible to the local community.[10] In Africa, they consume approximately 50% of financial and human resources and, as the training ground for most health workers, have a major influence on increasing capacity building within health systems. Here, both basic and slightly more complex cost-effective interventions are provided in a multiprofessional setting that concentrates skills and resources.[19,24] However, care has been suboptimal in many areas. Recent efforts to identify indicators of quality hospital care for critically ill children and newborns suitable for use in low-income settings have suggested availability of intravenous fluids, epinephrine for injection, presence of a triage system, and prioritization and grouping of severely ill children for increased observation as valuable indicators.[74]

Introduction of publicly funded ICU care should be targeted in countries with under-5 mortality rates less than 30 per live births. Building regional centers of excellence to grow publicly funded intensive care resources and capacity over time may be a reasonable first step. However, there is no approach to improve health care systems that is suitable for all countries, and not all approaches are congruent with local values and ideologies or acceptable to all governments or their constituencies. Thus health care strengthening must be seen as a long-term process that involves complex systems and requires carefully orchestrated action on a number of fronts.[75] In order to avoid development of distrust in health care systems by local communities, focus on quality of care and its measurement are key for enhancing critical and intensive care services in resource-limited settings. The quality of care approach should include safety, effectiveness, and care delivery in ways that respect the dignity of individuals in the context of their own "local moral worlds."[76]

In recent years, the funding landscape has changed dramatically, and there is extensive private participation in the health care systems of LMICs, especially in service delivery. The private sector ranges from a limited number of formal not-for-profit and for-profit providers to numerous informal providers. There has been an increase in the number of private providers, driven by both rising incomes and the failure of public services to meet expectations.[69] The engagement of the private sector is a topic of considerable controversy, seen by some as inviting the privatization of health care and making it a commodity.[77] However, when the capacity of the public sector is limited and there is a concentration of human resources in the private sector, seeking a mix of public and private provision of services can be seen as a pragmatic response and may spur overall increases in services and care delivery.[78]

Capacity Building via Education

Most deaths among seriously ill children who come into contact with referral level health services occur within the first 48 hours of presentation.[79] Therefore, early recognition of critical illness and good quality immediate and effective care provided by skilled health professionals would likely reduce these deaths.[21,80] However, severe shortages of primary care providers, specialists, nurses, and prehospital-care providers remain a major challenge in LMICs. This crisis is exacerbated by the brain-drain of medical providers from resource-poor to resource-rich countries. To improve health workers' capacity to provide effective care for seriously ill newborns and children in low-income countries, various in-service life support training courses, based mainly on models of high-income countries, have been introduced in LMICs. These courses include (1) neonatal life support courses (eg, Newborn Life Support [NLS], Neonatal Resuscitation Program [NRP]); (2) pediatric life support courses (eg, Pediatric Advanced Life Support [PALS], Pediatric Life Support [PLS]); (3) advanced short courses in pediatric critical and trauma care (eg, Pediatric BASIC Course, Pediatric Fundamental Critical Care Support [PFCCS], and Advanced Trauma Life Support [ATLS]); (4) life support/emergency care elements within the Integrated Management of Pregnancy and Childbirth program (eg, Essential Newborn Care [ENC]); and (5) components of other in-service child health training courses that deal with the care of children with serious illness (eg, Emergency Triage, Assessment and Treatment [ETAT], Control of Diarrheal Diseases [CDD], and Acute Respiratory Infection [ARI] case management programs; training components of the Integrated Management of Childhood Illness [IMCI] strategy).

A recent Cochrane review assessed the effects of in-service emergency care training on health professionals' treatment of severely ill newborns and children in low-income countries.[81] It included only two neonatal resuscitation studies, both of which suggested a beneficial effect on health provider outcomes (resuscitation practices, assessment of breathing, resuscitation preparedness) in the short term. However, the effects on neonatal mortality outcomes were inconclusive, and improvement in health provider practices after training was not generalizable. The review authors concluded that decisions to scale up life support courses in low-income countries “must be based on consideration of costs and logistics associated with their implementation, including the need for adequate numbers of skilled instructors, appropriate locally adapted training materials and the availability of basic resuscitation equipment.”[81]

ETAT was developed by the World Health Organization, specifically aimed at low-income countries, and is intended to improve prompt identification and institution of lifesaving emergency treatment for very ill children. This course was adapted to the East African context as “Emergency Triage Assessment and Treatment Plus admission care” (ETAT+).[82-84] Despite some positive results of ETAT+ implementation and further dissemination of these guidelines and training, reports indicated significant variation in uptake of best practices.[20-22,35,85] In Kenya, health workers at the hospital level were unable to provide appropriate care for severely ill newborns or children with inadequacies in key tasks such as prescription of antibiotics and feeds even when resources were available.[26] In attempting to rectify these deficiencies in care, the level of engagement of senior and particularly midlevel clinical managers was important.[86] The simple availability of authoritative WHO and national guidelines alone therefore does not improve hospital care for children as hoped. Broader, more system-oriented interventions addressing the many important

influences on provider or user behavior are necessary.[73] A recent multifaceted approach addressing deficiencies in knowledge, skills, motivation, and organization of care utilizing face-to-face feedback of performance, supportive supervision, and provision of a local facilitator resulted in more sustained improvements of pediatric care in Kenya.[35]

The global community can help by supporting country-led processes of reform and capacity building in education and by helping to create a stronger evidence base that contributes to cross-country learning.

Critical Illness During Disease Outbreaks

As the recent H1N1 influenza, severe acute respiratory syndrome (SARS), and Ebola outbreaks have clearly illustrated, critical care resources are vital. With increasing global urbanization, the potential risks of emerging and reemerging infections grow, increasing critical care needs for large numbers of seriously ill patients.[87] Mass critical care preparedness in resource-limited settings has been largely ignored, despite the large densely crowded populations who are prone to suffer disproportionately from natural disasters.[88] A recent international consensus statement emphasizes the need to develop resilient health care systems. To prepare for disaster and mass critical care preparedness in resource-poor settings,[28] it recommends strengthening the primary care, basic emergency care, and public health systems and building critical care capacity in the fields with the highest burden of disease such as surgery, obstetrics, internal medicine, and pediatrics. To improve capacity building and quality of care at district hospitals, performance improvement activities should be instituted. District and regional level health centers should develop at least a minimal level of critical care. Prehospital care and transport of the critically ill could be improved through community-level education of medical and nonmedical laypersons.

How to Develop an ICU in Low- to Middle-Income Countries

Development of an ICU in LMICs should start with a needs assessment to build the care according to the local patient population needs, medical practices and culture, and available physical, equipment, and staffing resources.[89] For publicly funded ICUs, there should be early and close engagement with policy makers and administration to ensure long-term sustainability. Bed space sizes according to US standards[90] are likely not feasible in LMICs. However, because communicable diseases are highly prevalent in LMICs, adequate distance between bed spaces or a facility with separate isolation rooms needs to be taken into consideration.[91] Both adequate water and electricity supply are vital for an ICU. Backup power generators and equipment with prolonged battery life can help overcome temporary electricity shortages. Selection of ICU equipment (ventilators, monitors, blood gas machine, infusion pumps) for use in LMICs requires careful consideration of not only the initial cost but also the availability of ongoing maintenance and biomedical support from the supplier, cost of consumables (and their potential reusability), equipment durability, and ease of use.

Given the lack of trained critical care staff in LMICs, education of ICU nurses, physicians, pharmacists, and potentially respiratory therapists in basic critical and intensive care should be performed before opening ICU doors. Visiting content experts from high-income countries can play an important role in initial and ongoing capacity building. However, these trainers need to be well versed in the cultural context and should be educated on cultural sensitivity, the community, and medical problems of the host nation for the whole process to be effective.[89,92] Nursing staff turnover can be a challenge, leading to a significant burden of staff retraining.[67,89] In addition to ICU content, team work and organizational skills required for efficient ICU care need to be taught and maintained.

Given the limited ICU resources, their cost, and the principle of fee for service in many LMICs, an ethical framework including ICU patient inclusion and exclusion criteria should be set before ICU operation. Other important systems required for establishment of an ICU include infection control, reliable availability of medication and consumables (including their easy accessibility and restocking on code or procedure carts), radiology, laboratory medicine, and medical record systems that allow easy measurement of ICU patient outcomes.

Importance of Critical Care Research in Limited Resource Settings

Published data on critical care research from low-income countries remains limited yet is much needed.[9,67] Reasons for this gap in evidence may include lack of funding, lack of local critical care providers and researchers, lack of academic mentorship and infrastructure to do research, or barriers to turning available data into publishable research. The limited evidence in this field hinders effective and efficient care and advocacy for resources.

The research agenda should include increasing evidence regarding basic critical illness epidemiology and its outcomes in these settings. A more accurate estimate of the potential lives saved through critical care would serve to prove its role in health care systems in resource-poor settings.[10] Efficacy must be measured and validated for critical care interventions, with limited resources targeted to those practices that save lives, time, and resources. Dissemination of evidence and experience from successes and failures could help accelerate the pace of critical care infrastructure improvements. Data on critical care capacity and access to both critical care resources and health care professionals are essential for health system planning but generally lacking.

While recognizing that uptake of new recommendations can be slow in LMICs,[93] efforts should be made to adjust critical care guidelines from high-income countries to limited-resource settings including sepsis management guidelines.[18] Cost-effectiveness analyses of current and proposed critical care practices need to be emphasized.[67] Patient triage and clinical research would benefit from severity of illness scoring systems, adapted and validated for resource-poor settings. Low-cost critical care technology, such as low-cost mechanical ventilators[94,95] and noninvasive positive pressure ventilation, is much needed to support critical care in limited-resource settings. Locally available, ubiquitous technology such as cell phones should be used to enable better health care seeking and delivery and solve clinical

challenges. Production of equipment within low-income countries or LMICs, rather than expensive import from the United States and Europe, may help drive down the cost of critical care interventions in these settings.[96] Technology development must be tightly woven into solving implementation challenges that result from not only technology cost and availability but also complexity of the political, social, and professional systems in LMICs.[93]

CHAPTER 22

Educating the Intensivist

Mary W. Lieh-Lai, Denise M. Goodman, David A. Turner, Katherine Cashen

PEARLS

- Effective teaching should relate clearly to learners' current experience and knowledge.
- Adults learn best by active participation and practice; therefore educational efforts should emphasize these concepts and include bedside teaching, debriefing, simulation, case-based, and experiential learning.
- Skill acquisition in medicine is similar to the continuum of human developmental stages with learning that progresses from novice, advanced beginner, competent, proficient, expert, and, finally, master.
- The mature clinician is one who reflects on his or her daily medical experiences to place him or her in a larger context of previous encounters and critically evaluates his or her own performance, acknowledging both effective and ineffective aspects of patient care.

Pediatric critical care medicine is a discipline dedicated to the care of the critically ill child. The specialty focuses on the sick child as a whole and takes into account the impact of disease on all organ systems, addressing the physical, mental, and emotional needs of the child and those of his or her family. The education of pediatric intensivists is focused on patient care principles that include resuscitation, advanced life support, management of traumatic injury, postoperative care, application of mechanical ventilation, renal replacement therapy, cardiovascular support, and hemodynamic and neurologic monitoring. Knowledge of toxicology, pulmonology, hematology/oncology, and metabolic disorders; pharmacologic principles; transplantation; procedural sedation; and infectious diseases is also important. The complex needs of the critically ill child also require that intensivists be prepared to assume a leadership role in the coordination of care among team members from multiple disciplines (see Chapter 3). In addition, the pediatric intensivist must develop an understanding of the ethics of critical care medicine and be able to balance complex and high-technology care with humanistic principles and respect for the patient as a human being (see Chapters 14–16). The intensivist must be knowledgeable in patient safety and quality improvement methodology but should also lead these efforts in the intensive care unit environment (see Chapter 11).

Skills for evaluating medical literature, clinical and/or basic science research, and the ability to teach learners of different levels effectively are all invaluable.

Adult Learning

Stuart and Hubert Dreyfus developed a model of skill acquisition on the basis of their studies of fighter pilots.[1] The Dreyfus model proposes that skill acquisition is not different from the continuum of human development, with stages of skill acquisition designated as novice, advanced beginner, competent, proficient, expert, and, finally, master. The learner needs to acquire certain skills and learn certain concepts at each level; therefore teaching methods have to match the level of development (Table 22.1).[2]

TABLE 22.1

Dreyfus and Dreyfus Model of Skill Development Applied to the Development of a Competence in the Subspecialty of Critical Care Medicine

Level of Learning and Characteristics	Examples of Learner Level in Critical Care Medicine	Teaching Implications
Novice: Rule driven Uses analytic reasoning and rules to link cause and effect Synthesis of information is based on knowledge acquired during residency training Big picture elusive	FIRST-YEAR FELLOW: Interviews patient and performs a physical exam that is focused on the critical illness May not be able to focus the information on the basis of a differential diagnosis Does not see the big picture	Teach basic critical care concepts Point out subtle but meaningful diagnostic information in the history and physical examination Eliminate irrelevant information Highlight discriminating features and their importance to the diagnosis Encourage reading about 2 diagnostic hypotheses at the same time
Advanced beginner: Sorts through rules and information to decide what is relevant on the basis of past experience Uses analytic reasoning and pattern recognition to solve problems Able to abstract from concrete and specific information to more general aspects of a problem	SECOND-YEAR FELLOW: Can generate more specific differential diagnosis while obtaining history and physical examination Capable of filtering relevant information to formulate a unified summary of the case Can abstract pertinent positives and negatives from the review of systems and incorporate them into the history of present illness	Expose learner to clinical cases proceeding from common to uncommon Emphasize the use of semantic qualifiers Encourage formulation and verbalization of differential diagnosis and treatment plan Good coaching: help learner become attentive to the meaningful pieces
Competent: Emotional buy-in allows learner to feel appropriate level of responsibility More expansive experience tips the balance on clinical reasoning from methodical and analytic to identifiable pattern recognition of common clinical problems Sees the big picture Complex/uncommon problems still require reliance on analytic reasoning	THIRD YEAR: Recognizes common patterns of illness based on previous encounters Sees consequences of clinical decisions, which leads to emotional buy-in to learning Will methodically attempt to reason through complex or uncommon problems Responsible for decision-making process	Balance supervision with autonomy in decision making Hold learners accountable for their decisions Do not tell them what to do; ask what they want to do Critical for learner to see a breadth and depth of patient encounters to construct and store in memory a large repertoire of illness scripts Tip the balance from clinical reasoning to pattern recognition
Proficient: Breadth of past experience allows reliance on pattern recognition of illness	CLINICAL INSTRUCTOR: Starts to match findings with those encountered in past	Needs to work alongside and be mentored by an expert Must develop capacity to know

Problem-solving intuitive Still needs to fall back to methodical and analytic reasoning for managing problems because an exhaustive number of permutations and responses to management have provided less experience in this regard than in illness recognition Is comfortable with evolving situations, able to extrapolate from a known situation to an unknown situation Can live with ambiguity	experience Data gathering more effective and efficient Sees patient through different lens than the student Engages in process of clinical reasoning to find the best intervention	ones' limitations and step back and call on additional resources when stretched beyond one's capabilities
Expert: Thought, feeling, and action align into intuitive problem recognition and intuitive situational responses and management Open to notice the unexpected Clever Discriminates features that do not fit a recognizable pattern	ASSOCIATE PROFESSOR: Broad repertoire of illness scripts, based on clinical experience that allows immediate action for majority of clinical encounters Likes to deal with diagnostic dilemmas When presented with diagnostic dilemma, will slow down and look it up	Keep up the challenge Needs ongoing experience and ongoing exposure to interesting and complex cases to avoid complacency and to help transcend beyond this level Should be apprenticed to a master who models the skills of the reflective practitioner and a commitment to lifelong learning
Master: Exercises practical wisdom Goes beyond the big picture to that of culture and context of each situation Deep level of commitment to the work Great concern for right and wrong decisions that fosters emotional engagement Intensely motivated by emotional engagement to pursue ongoing learning and improvement Reflects in, on, and for action	ASSOCIATE PROFESSOR/ PROFESSOR: The clinician that everyone goes to with problem cases Recognizes subtle features of a current case reminiscent of cases seen over the years Painstakingly revisits past cases or identifies common thread that will help treat the current clinical problem Vision extends beyond individual practice Contributes to bigger context to improvements in the field Intense internal drive to learn and improve Practical wisdom	Self-motivated to engage in lifelong learning and practice improvement

Adapted from Carracccio CL, Benson BJ, Nixon LJ, Derstine PL. From the educational bench to the clinical bedside: translating the Dreyfus Developmental Model to the Learning of Clinical Skills. Acad Med. 2008;83:761-767.

In addition to this developmental approach, principles of adult learning are crucial in the development of a curriculum that creates understanding and utilization of the competency domains by trainees and practitioners. Adult learning is fundamentally different from childhood learning because of the greater depth and breadth of experiences and knowledge on which adults build with new experiences.[3,4] In order to assimilate new information, adults must be able to integrate new ideas with what they already know, and information that conflicts with this knowledge may not be quickly integrated.[5] Adults have varied experiences and knowledge and do not all learn in the same way. They learn best when they are active participants in the learning process and are allowed to practice newly acquired skills and concepts,[4,6] and a multimodal approach to teaching with multiple exposures to content is more effective than any single approach or exposure method.

Adults are also self-directed and autonomous. As a consequence, education is typically most effective when programs facilitate self-learning with specific goals of acquiring practical information. Motivation for learning is both intrinsic (personal need for new knowledge or skill set) and extrinsic (professional expectations from

colleagues or authority figures). Adults benefit from an appropriately challenging learning environment.[4,5] Finally, adult learners require and often seek out feedback, and they therefore learn more effectively when given timely feedback that reinforces newly acquired information.

ACGME Core Competencies

In 1999, the Accreditation Council for Graduate Medical Education (ACGME) initiated an outcome project to design a conceptual framework for education and training according to six general domains of competency.[7] The objective of the outcome project was to "ensure and improve the quality of graduate medical education (GME)."[8] The ACGME recommends that trainees demonstrate (1) *Patient care* that is compassionate, appropriate, and effective for the treatment of health problems and the promotion of health; (2) *medical knowledge* regarding established, as well as evolving, biomedical, clinical, and cognitive sciences with the ability to apply these concepts to patient care; (3) *practice-based learning and improvement* involving self-evaluation with regard to patient care, appraisal, and utilization of scientific evidence; (4) *interpersonal and communication skills* that result in effective information exchange and partnership with patients, their families, and other health professionals; (5) *professionalism* manifested through a commitment to professional responsibilities, adherence to ethical principles, and sensitivity to a diverse patient population; and (6) an awareness of and responsiveness to the health care system and the ability to utilize system resources to provide optimal care in a *systems-based practice*.[7] These core domains of competency should be used to guide and coordinate evaluation of all residents or fellows in their development.[9]

Methods of Teaching

The quality of education in training programs is critical to fellow development. The importance of program quality was demonstrated in a study by Asch et al., which included almost 5 million deliveries performed by 4124 obstetricians from 107 residency programs in the United States.[10] The ranking (in five quintiles) for residency training programs was generated for the risk-adjusted maternal complications outcomes. In order to ensure that there was no residency selection bias, a secondary analysis was performed on data from medical licensure test scores obtained from the National Board of Medical Examiners and the Federation of State Medical Boards. The authors found that women treated by obstetricians who trained in programs in the bottom quintile had major maternal complication rates one third higher than those obstetricians who trained in programs in the top quintile.

Given the complexity of the intensive care unit (ICU) environment and the wide range of learners and educators, those in charge of education should consider the importance of the quality of teaching methods. The faculty members responsible for supervision in the ICU are the content experts and are also expected to be the facilitators/educators for all learners. To be an effective educator, there must be a clear understanding that a gap often exists between educators and learners regarding perceptions of adequate teaching and optimal teaching techniques.[11] One must overcome recognized barriers to education, which include lack of dedicated teaching time, high clinical workload, and lack of continuity between faculty and

learners.[11-17] These factors are increasingly challenging in the current era of GME.[18]

Education in the ICU consists of teaching basic principles but should also include an ongoing, dynamic integration of new medical knowledge and technologic advances. In 2004, the Society for Critical Care Medicine released *Guidelines for Critical Care Medicine Training and Continuing Medical Education,* which addressed the needs of physician education in critical care medicine on a continuum from the resident to the intensivist. Table 22.2 demonstrates the broad scope of educational objectives for critical care medicine fellows and intensivists and includes two broad areas of learning: clinical and administrative.

TABLE 22.2

Methods Used in the Education of Physicians

Teaching Method	%
Bedside, case-based teaching	94.4
Lecture series	79.0
Morbidity and mortality conference	72.6
Syllabus of articles	63.7
Journal club	62.9
Multidisciplinary rounds	60.5
Rounding sheets	58.1
Web-based articles	29.0
Psychomotor skills laboratories	24.0
Full-body simulator	15.3
Cadaver/animal laboratories	8.1
Computer simulation	4.8
Palm pilot algorithms	3.2
Standardized patients	3.2

Adapted from Chudgar SM, Cox CE, Que LG, et al. Current teaching and evaluation methods in critical care medicine: has the Accreditation Council for Graduate Medical Education affected how we practice and teach in the intensive care unit? Crit Care Med. 2009;37:49-60.

Teaching tools should be designed and selected to optimize improvement of both physician performance and health care outcomes, and curricular development should focus on development of effective programs that include sequenced and multifaceted activities.[6] A review that evaluated 37 studies of continuing medical education activities demonstrated that the use of multiple media, a variety of instructional techniques, and exposures to content to meet instructional objectives are all needed to improve clinical outcomes.[19] A recent review of techniques in critical care demonstrates the importance and benefit of multiple interactive strategies[20] that apply principles of adult learning. A survey of critical care medicine program directors across several specialties (pediatrics, surgery, internal medicine, and anesthesia) was conducted to determine current teaching methods, and these are summarized in Table 22.3.[21] In this survey, the most common teaching technique in the ICU was bedside, case-based teaching, with 80% of programs spending at least 2 hours a day on this activity. Eleven program directors planned on implementing computer or human patient simulation (45%), and 50% would also incorporate web-based learning modules, which also have been shown to be effective.[22] Debriefing is another teaching strategy that is commonly integrated into simulation-based education and is increasingly being used within the context of clinical care in the ICU to teach important principles. A debrief is a review of a situation led by an experienced facilitator to allow learners to explore steps that went well and identify opportunities for improvement and learning.[23] Another survey of PCCM program

directors demonstrated that faculty role modeling is the most common technique used in pediatric critical care programs to teach the competencies of professionalism and communication.[24]

TABLE 22.3

Essential Clinical and Administrative Learning Points

Clinical	Administrative
Identify and teach others to identify the need for/provide care for all critically ill patients.	Evaluate ICU policies and suggest improvements.
Provide and teach others resuscitation for any patient sustaining a life-threatening event.	Triage critically ill patients to optimize care delivery within the institution.
Initiate, manage, and wean patients from mechanical ventilation and teach others new methods and devices for management of respiratory failure.	Improve resource utilization and maintain patient care quality by facilitating triage of patients to limited institutional critical care beds and caregivers.
Initiate critical care to stabilize and manage patients who require transport.	Develop programs and change unit practice to improve care of critically ill patients.
Instruct other qualified caregivers and the lay public in the theory and techniques of CPR.	Develop programs for patient safety monitoring and error reduction.
Treat cardiogenic, traumatic, hypovolemic, and distributive shock with conventional and state-of-the-art approaches.	Actively participate in quality assurance processes, including morbidity and mortality conferences, process improvement teams, and the Joint Commission preparation.
Recognize potential for multiple organ failure and institute measures to avoid or reverse this syndrome.	Support the process of assessing patient and family satisfaction and participate in tool development and implementation.
Identify life-threatening electrolyte/acid-base disturbances and provide treatment/monitor outcome.	Encourage and enhance good relationships with other health care providers.
Identify and initiate discussions involving ethical issues and parent/patients' wishes in making treatment decisions, using advance directives, and other methods.	Understand advanced concepts important for compensation of critical care services and contractual issues related to providing critical care services and performing the business of medicine.
Diagnose and treat common and uncommon poisonings.	Develop skills for teaching critical care.
Teach appropriate use and monitoring of procedural sedation and use advanced pain management strategies.	Develop and evaluate curriculum changes for ICU caregivers, fellows, and residents.
Diagnose malnutrition and use/monitor advanced nutrition support methodologies.	Evaluate, modify, and approve ICU hospital policies.
Provide invasive and noninvasive monitoring for titrating therapy. Prioritize complex data to support action plan.	Improve resource utilization and maintain patient care quality by planning for future needs for institutional and regional critical care resources.
Use and teach medication safe practice guidelines and determine cost-effectiveness of therapeutic interventions.	Develop programs and change unit, institution, and regional practice to improve care of critically ill patients.
Develop skills of ICU nurses and ancillary personnel in caring for critically ill patients and provide in-service education.	Use existing tool sets to assess patient and family satisfaction and direct the development of new tools when appropriate.
Use, teach, and help enforce methods of infection control.	Develop programs and document improvement in patient safety monitoring and error reduction.
Communicate effectively with patients, families, and other involved members of the health care team about all treatment decisions and patient prognosis.	Develop high-quality relationships with other health care providers.
Continue to augment knowledge by assimilating peer-reviewed published medical literature through self-directed learning and CME activities.	Teach the business of medicine.
Diagnose and treat a sufficient number of patients with critical illness using conventional and state-of-the-art approaches to maintain clinical proficiencies.	Develop collaborative and productive relationships with other specialist physicians and model joint clinical planning in managing complex ICU problems.

Adapted from Dorman T, Angood PB, Angus DC, et al. Guidelines for critical care medicine training and continuing medical education. Crit Care Med. 2004;32:263-272.

Some methods of teaching are particularly important in the ICU. These include case-based learning and experiential learning, both of which are based on principles of adult learning. Case-based learning uses scenarios or cases to address a particular curricular element and can be applied individually or in small group discussions. A

faculty member who has the expertise to stimulate participants to think about the knowledge and skills necessary to “solve” the case and eventually apply that to future practice generally leads the discussion.

Experiential learning is thought to be one of the most important ways by which medical students, residents, and fellows acquire clinical knowledge and skills. Kolb[25] and Atherton[26] described experiential learning as a cycle composed of four stages that include concrete experience, reflection, abstract conceptualization, and active experimentation. Concrete experience or knowledge by acquaintance is where the learner is directly exposed to something and then reflects on what the experience means to him. Subsequently, the learner can apply theories that he or she has learned and use this information to modify his or her approach to future clinical encounters.

Teaching at the Patient's Bedside

In 1968, Reichman et al. demonstrated a 75% “incidence” of teaching at the bedside during attending rounds.[27] That number had declined to 16% in 1978[28] and may be lower today. Almost 20 years ago, LaCombe[29] expressed concerns about bedside teaching that remain today. “Profound advances in technology, in imaging, and laboratory testing and our fascination for these aspects of patient care, account for part of this decline, but faculty must also assume responsibility for the present lack of bedside teaching. If we are to reverse this trend, we will need to realize the barriers to bedside teaching, both real and imagined, and overcome them. And if we are to become effective bedside teachers, as were our mentors, we will need to sharpen our own physical diagnostic skills. We will need to learn how to be gentle with students and house staff, how to better communicate with patients, and how to teach ethics and professionalism with the patient at hand.”

Very few data exist on the frequency of bedside teaching in the ICU in the modern era of medical education. Experiential learning and case-based learning at the bedside are traditionally thought to be the most effective means of educating clinicians in the understanding of disease processes and evaluation and management of critically ill patients. The impact of experiential learning at the bedside caring for a patient with fulminant meningococcemia and purpura fulminans is extremely valuable and difficult to quantify. Less dramatic but potentially equally effective are instances when one palpates a thrill, hears a gallop, feels an enlarged liver or spleen, listens to wheezing or stridor, or performs a detailed neurologic examination in a patient who has experienced a stroke or a spinal cord injury. Medical technology can be leveraged to enhance bedside teaching, as when flow-volume loops in a child with asthma are used to teach the principles of mechanical ventilation in the setting of bronchospasm or the waveforms on bedside monitors allow a demonstration of the impact of ventilation on hemodynamics. Showing learners extracorporeal membrane oxygenation circuits, continuous venovenous hemodialysis and ultrafiltration machines, high-frequency ventilators, and ventricular assist devices while they are being used in patient care reinforces prior learning and may provide the “aha” moment that is difficult to recreate in didactic lectures.

In addition, when trainees present the historical data and physical findings of their patients to the attending physician and the team during bedside rounds, they can be taught to describe the information relating to their patients in a succinct manner and discriminate between important and less important information, develop a list of

differential diagnoses, and formulate a treatment plan. Bedside and experiential learning teach the important skill of “thinking on their feet,” which will assist in their drawing correct conclusions regarding diagnosis and making management decisions. Bedside teaching and rounds are also important for the demonstration and role-modeling of professionalism (see also Chapter 2).

In the current era of limited duty hours and excessive time required for electronic medical recordkeeping, the focus on teaching and care of the patient at the bedside is sometimes lost.[30,31] However, it is important to remember that patients are often our best teachers, and developing into an outstanding practitioner hinges on exposure to a large and varied number of clinical situations to develop all of the domains of competency.

Procedural Training

Procedural expertise is crucial in the care of critically ill children. Specific skills that must be acquired during fellowship include peripheral arterial and venous catheterization, central venous catheterization, endotracheal intubation, thoracostomy tube placement, and procedural sedation (see Chapters 19 and 20).[32] In addition, knowledge of the indications, techniques, limitations, and complications of other procedures including cricothyroidotomy, tracheostomy, pericardiocentesis, and abdominal paracentesis is recommended.[33,34] Wide-ranging approaches to teaching procedures include didactics, video- and web-based training, and simulation. Regardless of the specific techniques implemented, initial performance under direct supervision is paramount, with progressive development of autonomy through the course of fellowship training.

Simulation Training

Simulation training is an interactive technique used to replicate real-world situations and experiences.[35] Historically, medical skills were developed by practicing on animals and cadavers, and sometimes this “practice” even occurred on actual patients. However, concerns regarding patient safety, quality of care, and ethics, along with advances in simulation technology, have led to a substantial increase in the use of simulation in medical education.[36-38] Modern medical simulation originated in the early 1960s with simple resuscitation manikins that were used in the field of anesthesiology, and this technique has both expanded and evolved substantially over time. Technologic advances in computer programming and manikin development, as well as increased affordability, have contributed to increasing use of this educational modality.[39]

Medical simulation can be generally divided into five different categories: role play, standardized patients, partial task trainers, computerized patients, and electronic patients. The most comprehensive form of simulation training is the electronic patient or high-fidelity, instructor-driven manikin.[35] These manikins are programmed to display normal and abnormal physical examination findings. The training session is divided into three sections: prebriefing, scenario exercise, and debriefing. Debriefing plays an important role in the educational process and allows the instructor to reemphasize the objectives of the exercise and address knowledge gaps that may have been unmasked during the scenario, and it allows the trainees to reflect on performance and discuss areas for improvement.[40-43]

Simulation training in medical education has gained widespread acceptance as a result of the ease of simulating critical events, safety of the learning environment, and reproducibility of the clinical scenarios.[44] Learners practice and develop skills without the consequences of negative patient outcomes. For procedures that are performed infrequently, simulation allows repeated opportunities to practice. Scenarios can be created to simulate a range of complications that the learner might otherwise not witness or experience. Recent evidence demonstrates that learners enjoy participation in medical simulation, and individual and team member performance are enhanced. In addition, self-confidence, knowledge, and operational performance improves with simulation training.[45-48] Some centers have implemented intense simulation-based orientation training for first-year pediatric critical care medicine fellows.

Other novel approaches for procedural training include senior pediatric resident–led mock code curricula use of "action-linked phrases" and real-time feedback during simulation.[49-51] Simulation-based medical education with deliberate practice to attain constant skill improvement is superior to traditional clinical education for acquisition of a wide range of medical skills.[52]

In-Situ Simulation

The ICU is a highly dynamic setting with complex patients and frequent high-risk situations and invasive procedures that need a well-functioning multidisciplinary team. In-situ portable simulation provides the added advantage of replicating the true working environment of the ICU. The learners are placed in the patient care setting and have the opportunity to use the actual equipment within the environment in which they work. In-situ simulation has been used to identify safety threats and reinforce resource location and teamwork behaviors.[53] It allows multidisciplinary team training in the setting of their clinical work.[54]

From the traditional code team to the performance of high-risk procedures, personnel must work together to accomplish many tasks. Training in teamwork and communication, known as Crew (or Crisis) Resource Management (CRM), was developed and implemented in the aviation industry to reduce or eliminate the contribution of human errors to catastrophic events. These principles have been adapted for use in anesthesia crisis management protocols and focus on competent team management, dynamic decision making, interpersonal behavior, situational awareness, effective use of resources, and stress management.[55] CRM training improves team functioning and dynamics in pediatric intensive care settings.[56-58] Clinical skills acquired during medical simulation have been shown to directly improve patient care practices and may improve patient outcomes.[44]

The effects of simulation on patient outcomes are more difficult to quantify due to multiple confounding factors. However, refresher training and practice for central venous catheter maintenance care on manikins and patients were associated with fewer central line–associated bloodstream infections in one pediatric intensive care unit (PICU).[59] The introduction of a pediatric medical emergency team with concurrent simulation team training was associated with improvements in patient outcomes related to more rapid recognition and timely management of patients with clinical deterioration.[60] A simulation-based mock code curriculum for pediatric residents has been associated with subsequently improved survival rates in children who required cardiopulmonary resuscitation.[61]

Additional studies are needed to identify the optimal modality, frequency of exposure, quality of assessment tools, and impact of simulation education on patient care. A multicenter pediatric network (International Network for Simulation-based Innovation, Research, and Education [INSPIRE]) has been formed to measure the impact of simulation on clinical outcomes. Despite some limitations, simulation training remains an important adjunct to traditional medical education in the ICU.

Web-Based Education

In recent years, online and web-based approaches to education have continued to become more prominent and are especially important for the current generation of learners.[62,63] Numerous resources that use technology for both content and process are available for learners. Information is now readily available and can be accessed from computers, tablets, and smart phones[64] including traditional textbooks and materials and a wide range of specifically developed online tools such as "podcasts," online modules, and complete online courses. Web-based distance education programs have been created, an example of which is OPENPediatrics, which is focused on bringing pediatric critical care education to the global community.[64] The "flipped" classroom approach to education wherein the learner engages in self-study before a classroom session to apply and consolidate learning is becoming more prominent as it often better meets the complex scheduling needs of learners in medicine.[62,63,65]

Teaching Professionalism

Professionalism is one of the competency domains used by ACGME and American Board of Pediatrics (ABP) and is arguably one of the most highly valued attributes of the accomplished clinician (see also Chapter 2). The first challenge is to arrive at a common definition, taking into account the complex culture of the PICU with its diverse interprofessional teams, encompassing different disciplines (nurse, intensivist, surgeon, pharmacist, etc.), hierarchies, and generations (baby boomers, Gen X, Millennials), as well as personal characteristics of the many individuals (individual personalities, experiences, and culture).

Professionalism incorporates mutual trust, as the patient must trust the clinician, the clinician trust the patient, clinicians trust each other, and all trust the system in which they practice. Moreover, professionalism requires self-insight as one is continually required to assess personal responses to the challenges of critical care practice and reflect on the interrelatedness of experiences at work and in one's personal life. Most importantly, professionalism is a continuum, for just as our understanding of character and integrity develops throughout our lifespan, the application of these attributes to professional practice also matures over time. The ACGME definition of professionalism incorporates the attributes of altruism, compassion, honesty, and integrity. Ethics, accountability, and respect are also counted among the core values of professionalism. Taken together, professionalism is a social contract wherein the professional pledges a duty to service over self-interest.[66-78]

Can professionalism be taught? The answer is an emphatic yes, and not only can it be taught, it must be taught. In the absence of a formal curriculum, these principles will be taught by the so-called hidden curriculum, which is a well-described

phenomenon composed of the unwritten rules and assumptions, behaviors and attitudes, and accepted norms that are transmitted through informal interactions and hallway conversations. This hidden curriculum may be a powerful force for acculturation and exert a subtext even in the presence of a rigorous curriculum. That subtext may support or undermine the formal curriculum. For example, the principle that all patients should be treated with respect may be negated if derogatory comments about certain groups are common. To successfully teach professionalism, there must be explicitly articulated goals and expectations, as well as specific experiences through which to explore and apply key values, with sufficient guided reflection to integrate the concepts. A number of surveys and assessments have demonstrated that role modeling is one of the principal methods by which professionalism is taught, but this approach more likely reflects a reliance on ad hoc experiential learning. In fact, the identification of a role model rests with the learner, who recognizes someone as an exemplar whose behavior should be emulated. More commonly, the resident or fellow is expected to learn professionalism by watching the behaviors of his or her faculty, but this is inadequate if done without intentionality and a mindful reflection of a given clinical encounter. At a minimum, faculty should take trainees aside after a variety of clinical encounters to reflect on what went well and what could improve. It is also important to note that a wide range of approaches including interactive seminars, standardized patients, reflective writing, and others can be successfully applied to teaching professionalism.

Professionalism can also be evaluated, and a variety of outcomes can be used to assess the impact of a specific curriculum. Some of these outcomes reflect everyday mundane activities but provide a sense of responsibility and accountability, such as timeliness of completing requests or replying to queries. Others are more difficult to quantify, but multisource feedback from interprofessional team members and families is helpful.

The concept of professionalism has evolved with time, societal changes, and changes in health care delivery, and this evolution will continue. Limitations on trainee duty hours have led to concerns regarding the balance between trainee self-care and limited patient contact time, potentially undermining trusting relationships. External events and forces, such as the proper role for social media, will also require continual consideration of appropriate professional behavior. Notwithstanding these challenges, medicine has moved beyond an implied assumption that professionalism is a given and now recognizes that it must be a focus of education and development throughout one's career.

Education in Research, Scholarship, and Leadership

Education in research and scholarship is an integral component of becoming a pediatric intensivist, as evidenced by the requirement for meaningful scholarly activity for board certification by the ABP and emphasis on faculty scholarly activity as a key component for fellowship program accreditation by the ACGME. Research in pediatric critical care is discussed in detail in Chapter 7, but education in this area should include a breadth of experiences. In addition to teaching basic techniques for laboratory and clinical investigation, research curricula should include conducting an efficient literature review, understanding evidence-based medicine techniques,

presenting scientific findings, and medical writing. Trainees should not only learn these important skills but also begin developing techniques and approaches to teaching them.

In addition to research and scholarship, the pediatric intensivist has a central role in the education of his or her peers and team members while also managing ICUs and coordinating teams who provide multidisciplinary care to critically ill patients (see also Chapters 3 and 5). Leadership skills are crucial for every intensivist in both informal experiences (rounds, daily management of the ICU, crisis management) and formal administrative roles (committee chairs, medical director) (see also Chapter 2). In spite of these common leadership roles of intensivists in the ICU and hospital environment, specific curricula within training programs are often lacking.[79] A recent survey of multidisciplinary PICU team members demonstrated significant variation in the perceived importance of various leadership qualities for a pediatric intensivist. The field of leadership science is well developed outside of medicine, and education in this area represents an opportunity for research to determine how the myriad leadership theories and models apply to the ICU environment and the pediatric intensivist.

Education in Safety and Quality for Learning and Patient Care

While medical errors have been attributed to the fatigue of residents,[80] this is only one of many contributing factors. Others include lack of supervision, deficiencies in transitions in care, lack of education related to quality improvement, and issues related to the lack of professionalism. A survey conducted by the American Hospital Association[81] found that there is a significant deficiency in communication, systems-based practice, and interprofessional teamwork in recent graduates of training programs. The Institute of Medicine report "To Err is Human" stated that errors are more commonly caused by system-related factors that led to either mistakes or the failure to prevent them. It is therefore imperative that the educational curricula of residents and fellows include an integrated approach to address the six focus areas recently outlined by the ACGME Clinical Learning Environment Review process (Table 22.4). When residents and fellows learn the principles in safety and quality and integrate them into their work during training, it is highly likely that they will include these principles in their everyday practice long after the completion of training (see also Chapter 11).

TABLE 22.4

Patient Safety and Quality Improvement Focus Areas

Focus Area	Opportunities for Education
Patient safety	Reporting errors, unsafe conditions, and near-misses; participation in interprofessional teams to promote and enhance safe care
Health care quality	Involvement in institutional efforts to improve systems of care, reduce health care disparities, and improve patient outcomes
Transitions in care	Effective standardization and oversight of transitions of care
Supervision	Appropriate-level specific supervision
Fatigue management and mitigation	Oversight of duty hours, fatigue management, and mitigation and effect education with regard to fatigue recognition and mitigation
Professionalism	Behavior of residents, fellows, and faculty members in fulfilling educational and other

	responsibilities; truthfulness in scholarly activities; ethical and respectful treatment of patients

Evaluation and Assessment of Competency

Epstein and Hundert[82] define competence as the "habitual and judicious use of communication, knowledge, technical skills, clinical reasoning, emotions, values, and reflection in daily practice for the benefit of the individual and community being served." They further state that "competence builds on a foundation of basic clinical skills, scientific knowledge and moral development" and propose that competence is made up of several dimensions, each with a separate set of skills. Over time, a range of assessments has been utilized, including subjective assessment by supervisors, multiple choice examinations to evaluate factual knowledge and abstract problem-solving, and standardized patient assessments of physical examination and technical and communication skills. More recently, there is an increasing use of simulation-based assessment of competency. However, the evaluation of the ability to apply knowledge to patient care, the capability of working as a team member, and the development of physician-patient relationships can only be assessed by direct observation of real-life patient interactions. Pangaro[83] summarizes the issue of assessing competence very well: "The assessment of competence requires a whole series of performances that, in each moment of interaction with a patient, the competent physician must bring many qualities to bear, and what they will require varies from patient to patient."

Milestones

In order to fulfill the promise of the Outcome Project[84] to use educational outcome data in accreditation, milestones assessments in each specialty were developed by the ACGME in close collaboration with the members of the Review Committees, American Board of Medical Specialties (ABMS) certifying boards, medical specialty organizations, program director associations, and residents. Milestones describe the performance levels residents and fellows are expected to demonstrate for skills, knowledge, and behaviors in the six competency domains. They provide a framework of observable behaviors and attributes associated with the development of residents and fellows as physicians (Table 22.5, sample milestones template). The use of milestones assessment has a number of benefits for residents and fellows, and these include increased transparency of performance requirements by more explicit expectations, better feedback, and enhanced opportunities for early identification of underperformers.

TABLE 22.5

Sample Template for Milestones Reporting

GATHERS AND SYNTHESIZES ESSENTIAL AND ACCURATE INFORMATION TO DEFINE EACH PATIENT'S CLINICAL PROBLEM(S). (PC1)				
Critical Deficiencies			**Ready for Unsupervised Practice**	**Aspirational**
Does not collect	Inconsistently able to	Consistently	Acquires accurate	Obtains relevant historical

accurate historical data. Does not use physical examination to confirm history. Relies exclusively on documentation of others to generate own database or differential diagnosis. Fails to recognize patient's central clinical problems. Fails to recognize potentially life-threatening problems.	acquire accurate historical information in an organized fashion. Does not perform an appropriately thorough physical examination or misses key physical examination findings. Does not seek or is overly reliant on secondary data. Inconsistently recognizes patients' central clinical problem or develops limited differential diagnoses.	acquires accurate and relevant histories from patients. Seeks and obtains data from secondary sources when needed. Consistently performs accurate and appropriately thorough physical examinations. Uses collected data to define a patient's central clinical problem(s).	histories from patients in an efficient, prioritized, and hypothesis-driven fashion. Performs accurate physical examinations that are targeted to the patient's complaints. Synthesizes data to generate a prioritized differential diagnosis and problem list. Effectively uses history and physical examination skills to minimize the need for further diagnostic testing.	subtleties, including sensitive information that informs the differential diagnosis. Identifies subtle or unusual physical examination findings. Efficiently uses all sources of secondary data to inform differential diagnosis. Models and teaches the effective use of history and physical examination skills to minimize the need for further diagnostic testing.

Mentorship

And so it's been for me these long years. I've carried my mentor everywhere. If I get sloppy, I wonder "What would he think of me now?" And if I'm in a tight spot clinically, he prods me back to the literature. When I'm impatient with patients, I remember his patience with me. When I'm asked to teach, I do so willingly because that is what he did. When I begin to doubt myself, I remember his belief in me. And if I am ready to quit, I can see him standing there before me in his long white coat, with stern look and stethoscope, and I go on. What has he been for me, this mentor of mine? He's been like a father to me, but more than a father. He has been my companion in medicine, to help me through the loneliness that medicine can bring and to share with me the joy that medicine can be. My mentor has, through me and those of my students, cared decently and compassionately for countless patients. When I have cured a patient or two, why, so has he.

Michael A. LaCombe, MD, FACP

William Morgan Teaching Symposium,

University of Rochester, July 20, 1989

Mentorship is defined as a "dynamic, reciprocal relationship in a work environment between an advanced career incumbent (mentor) and a beginner (protégé), aimed at promoting the development of both."[85] Mentorship is at the core of the training of medical students, residents, and fellows in patient care, research, and education.

While the benefits to the mentee are often emphasized, it is clear that mentors benefit as well[86,87] as they tend to have greater satisfaction in their careers. Mentorship takes place at many levels. It may begin during medical school where a mentor guides and even inspires a student to choose a certain career path. During fellowship, a mentor can be a major contributor to the development of the trainee's clinical knowledge and patient care skills. In addition, if the fellow decides to pursue a career that includes research, the mentor can help identify a research focus and provide guidance in the entire process. For junior faculty members, mentorship provides opportunities to fine-tune clinical skills and diagnostic and therapeutic acumen. Research productivity is further enhanced by guidance in conducting basic science experiments and clinical trials, presenting findings, writing manuscripts, and obtaining extramural grant support. The mentor can help academic development of junior faculty members by sponsoring them for local, state, and national presentations or committee memberships and enlisting them as coauthors for book chapters and review articles. Mentorship in teaching is important as well. The mentor can help fellows and junior faculty members develop teaching skills by serving as an example and providing critique of teaching methods.

Although the importance of mentorship in academic development is clear, the process of finding the right mentor and developing the mentor-mentee relationship is altogether much more difficult. First, the mentee must decide his or her current and best sense of future goals before searching for his or her mentor. Junior faculty members should be provided with resources such as lists of senior faculty members who have successfully provided mentorships and what their areas of interest are. They should meet with many members of the department to determine who might be the best match. If no one in the department seems to fit that role, the mentee may need to look beyond his or her home institution. Perseverance is essential. Sometimes more than one mentor is necessary: One might serve as a clinical mentor and another for research activities. A forum should be available to junior faculty members to discuss their academic needs and concerns. Occasionally, when the mentoring relationship does not work out, the mentee should be allowed to seek out other mentors without being made to feel that it is wrong to do so. Academic departments should also foster mentorship by providing support for mentors including faculty development courses and recognition for their efforts.

Requirements

American Board of Pediatrics

The required elements for the education and training of pediatric intensivists in patient care have been defined over time and continue to evolve (see Chapter 1 for the history of the specialty). The ABP and sub-board of the Pediatric Critical Care Medicine have developed a list of content specifications for the subspecialty examination. This list is not intended to serve as a curriculum, but the pediatric intensivist sitting for the examination is expected to be familiar with more than 2000 items categorized into subsections and updated as the specialty evolves (https://www.abp.org/sites/abp/files/pdf/crit2010.pdf). To qualify for the ABP subspecialty examination, applicants are required to have a valid unrestricted allopathic and/or osteopathic license to practice, initial certification in general

pediatrics, and successful completion of critical care medicine training in a program accredited by the ACGME. The applicant must also provide evidence of meaningful research during training.

Following initial certification, the Maintenance of Certification (MOC) program ensures that the intensivist invests in ongoing knowledge and skills necessary for the delivery of quality care. MOC is based on six competency domains that are evaluated during fellowship training and includes four parts: Part I—professional standing (medical license); Part II—lifelong learning and self-assessment; Part III—passing an examination; and Part IV—performance in practice with participation in ABP-approved quality improvement activities in patient care. Lifelong learning and MOC are detailed in Chapter 23).

Accreditation Council for Graduate Medical Education

Pediatric Critical Care Medicine is one of the subspecialties accredited by the ACGME. Accreditation and oversight for the training programs are provided by the ACGME Pediatric Review Committee. Program accreditation centers on the six competency domains noted earlier in this chapter, which were developed by the ACGME and the ABMS. These domains of competence are designed to provide a framework for education and training of fellows. In addition, meaningful scholarship by faculty members and fellows, requisite faculty credentials, and appropriate faculty-to-fellow ratio are components of accreditation. Program faculty must have an active role in the training program and research productivity. Fellowship training requirements include but are not limited to defined patient variety and numbers, with an adequate opportunity to develop procedural competence, a didactic curriculum that is comprehensive and regularly implemented, formal education related to developing teaching skills, and evaluation of competency.

Maintaining Competency After Training

In reviewing ratings of performance, Williams and colleagues[88] quote the work of Kane, defining clinical competence as embodying aspects of knowledge, skills, and judgment referable to the situation under observation but also generalizable to similar clinical situations. From this perspective, the six competency domains form a useful framework by which the practicing clinician may structure self-directed education and a program to integrate reflective practice into all aspects of professional development.

Medical knowledge and patient care encompass foundational knowledge, technical facility, and professional judgment. The conventional means to assess knowledge is through a certification examination. Technical competence may be assessed indirectly, such as through chart reviews, resource utilization, or case logs, or directly, including videos of patient encounters, standardized patients, and skills labs. The latter, while often used for trainees, is not practical for practicing physicians. Another approach is the establishment of a minimum number of procedures to be completed, but the number is usually set by consensus expert opinion and rarely validated. Arbitrary numeric standards disregard the variability in rates of acquisition and maintenance of skills between individuals. With any

method, the data used to assess competence must meet several standards: The information must be accurate; observers and interpreters must agree on the implications of the findings; the observations must apply to a range of situations; and the tools must be feasible to use.[88] Once a skill is acquired, several factors influence maintenance of competency, including repetition, exposure to the procedure in different clinical situations, overall technical facility, and clinical judgment. Clinical judgment skills embody tangible and intangible qualities, including knowing when to perform or defer a procedure and recognizing when conditions deviate from the expected.[88]

Medical judgment in actual practice requires the application of knowledge to complex clinical situations, which rarely reflect the idealized descriptions of textbook medicine. Research in medical decision making shows that two major modes enter into these decisions.[89,90] Croskerry describes two phenotypes,[89,90] one of which is “intuitive, automatic, fast, frugal, and effortless.” An example might be pattern recognition that a patient is following an expected trajectory of illness. A second approach described by the same author is “analytical, deliberate, slower, costly, and effortful,[90] for example, the classic diagnostic dilemma, where critical pieces of data are not concordant with our assumptions regarding the disease process. Unfortunately, it is human nature to undervalue information that differs from our preordained conclusions and to overvalue confirmatory information. The experienced clinician is ever vigilant for misapplying System 1 style when more cautious analysis is warranted, or vice versa.[89,90] Encouraging fellows to develop this habit of vigilance is challenging but essential.

The competency domains of practice-based learning and systems-based practice serve as a framework to reflect on one's clinical experiences and refine both thought patterns. The most common forum for this approach is morbidity and mortality conference where the context in which decisions were made is an essential part of the review.[91-94] However, many other opportunities exist, including, among others, daily rounds and case-based education sessions.

Communication is often cited as the most important factor in both good and bad outcomes. While good communication is sometimes believed to be an innate personality characteristic, communication skills can be taught, and one's life experiences can lead to more active, empathetic listening and responses (see also Chapter 4).[92,95]

The end of formal training as a fellow represents the beginning of a lifelong process of obtaining and refining one's knowledge and judgment, constituting the essence of professional development and maintenance of competency. While the medical profession and society at large have historically assumed physician proficiency by virtue of their continued practice, it is dangerous to assume that longevity is tantamount to expertise. Instead, the mature clinician is one who reflects upon his or her daily medical experiences to place him or her in a larger context of previous encounters; critically evaluates his or her own performance, acknowledging both effective and ineffective aspects of patient care; and seeks to fill in gaps in knowledge or performance.[43,47]

Critical care is practiced in an atmosphere of innate uncertainty. In this environment the practicing intensivist must be able to adapt “on the fly” and also, once a situation is resolved, to step back and pursue generalizable knowledge for the next encounter.

Another aspect of lifelong learning is the role teaching plays in ongoing self-directed learning. By reviewing and synthesizing contemporary literature, whether for a didactic lecture or for family and patient information, the seasoned intensivist creates an opportunity to address all aspects of professional development.

The ABP has incorporated this template of professional development into its Maintenance of Certification program. Over time the framework of the six competency domains will become an integral part of ongoing professional development. Rather than viewing these as administrative hurdles, the wise clinician may view them as reminders of the many facets of professionalism and learning that medical practice requires (see also Chapter 23).

Acknowledgment

We gratefully acknowledge the contribution of Drs. Melinda Fiedor Hamilton and Kevin M. Valentine, who coauthored this chapter in previous editions.

CHAPTER 23

Lifelong Learning

Carrie A. Phillipi, Laura Marie Ibsen

PEARLS

- Adult learners are internally motivated to learn and have different styles and processes by which they learn.
- Active learning can occur in a variety of formats, including team-based, problem-based, simulation, and didactic teaching.
- Competency-based assessment is prominent in educational reform.
- Entrustable professional activities describe an *ability* to perform a task or responsibility without direct supervision once sufficient competency is attained.
- Milestones provide behavioral descriptors that indicate developmental progression along competencies.
- Educators and certification/accreditation bodies are piloting competency-based versus time-based progression in medical education and new assessment methods for physicians and trainees.
- Continuing medical education and maintenance of certification programs are working together to incorporate adult learning principles.

Lifelong Learning

The phrase *lifelong learner* implies the described individual has a voluntary interest in self-development and learning for pure enjoyment. It is assumed this attribute can be molded and influenced, even developed and promoted. These themes are prevalent in early childhood education. Montessori educational philosophy assumes a child is thirsty for knowledge and capable of initiating learning within a supportive learning environment.[1] Waldorf schools take a developmental approach to the child, taking advantage of natural tendencies in children to explore the natural world, arts, and sciences.[2] Adult learning principles build on these tenets.

Adult Learning Theory

Adult learning theory was theorized and modeled by Malcom Knowles in the 1970s.[3] He identified six principles of adult learning:

- Adults are internally motivated and self-directed.
- Adults bring life experiences and knowledge of learning experiences.
- Adults are goal oriented.
- Adults are relevancy oriented.
- Adults are practical.
- Adult learners like to be respected.

Given these general principles, Knowles drew on the work of Kolb,[4] where adult learning theory does not mean there is a one-size-fits-all approach to learning. For example, imagine two individuals who purchase a new electronic device. Whereas one may take the device out of the box, immediately turn it on, and begin experimenting with its features, the other purchaser may not even remove it from the box before reading the entire instruction manual. Adult learning theory celebrates the differences in learning approach, while making them overt and explicit. In designing and implementing curricula and assessments, medical educators may design curricula and evaluations attentive to these concepts (Fig. 23.1). Kolb described effective learning as a progression through a cycle of stages—having a concrete experience, reflection on that experience leading to information synthesis and future testable hypotheses. For those familiar with quality improvement principles, it is not unlike Plan-Do-Study-Act,[5] where small tests of change are implemented, observed, and the necessary modifications determined.

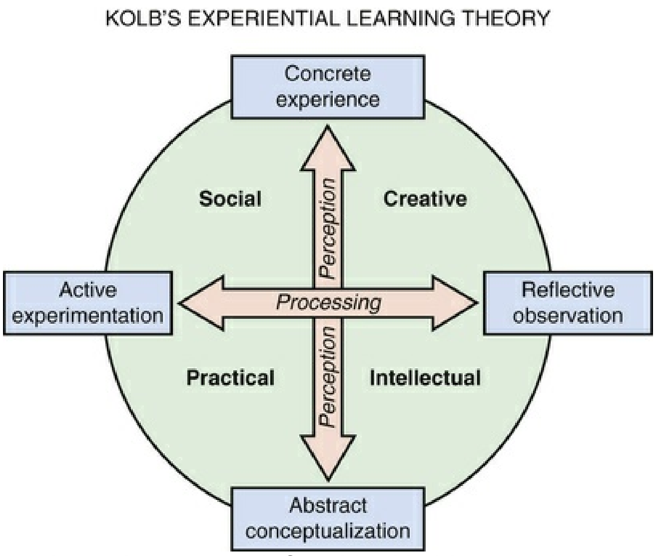

FIG. 23.1 Learning styles defined by Kolb's experiential learning theory. (Adapted from Kolb DA. Experiential Learning: Experience as the Source of Learning and Development. Upper Saddle River, NJ: Prentice-Hall; 1984:141.URL: http://www.learningfromexperience.com/images/uploads/process-of-experiential-learning.pdf. By Schaller DT, et al. One size does not fit all: earning style, play, and on-line interactives. In: Trant J, Bearman D, eds. Museums and the Web 2007: Proceedings. Toronto: Archives & Museum Informatics, published March 31, 2007, at http://www.archimuse.com/mw2007/papers/schaller/schaller.html.)

Applying Adult Learning Theory to Medical

Education (Learner Assessment Drives Teaching Methods)

Learner assessment drives teaching methods in medical education and is increasingly incorporating adult learning theory. Adult learning theory places an emphasis on problem-based, collaborative learning, as opposed to didactic learning, and equality between teacher and student. Efforts to be inclusive of curricular methods that support adult learning principles are occurring in undergraduate, graduate, and continuing medical education. Problem-based and small group learning, flipped classrooms, and simulation exercises allow us many venues for reaching learners in different ways. Didactic learning is also firmly in place. It should be emphasized that no one method of instruction has been definitively proved to produce better learning outcomes than another. Although one would hypothesize that a more collaborative or at least student-centered approach to teaching would improve knowledge, teamwork, and patient outcomes, this has not been universally demonstrated.[6,7,8] There are real costs to implementing and sustaining problem-based learning, flipped classrooms, and simulation. Instructor time and resources for small group learning and simulation scenarios are expensive. Standardized patients, simulation, and case-based learning may also feel scripted, without the nuances of social dynamics present in everyday clinical encounters. Table 23.1 depicts varied instructional techniques with potential benefits and costs.

TABLE 23.1

Instructional Techniques According to Potential Costs and Benefits

			Potential Benefits	Potential Costs
Didactic learning	Traditional Lecture	Teacher led	Easy to organize Inexpensive (both in teacher time and facility cost) Allows for independent learning	Noninteractive Noncollaborative
Problem-based learning	Small group cases	Student led Teacher facilitated	Active learning Motivation for learning Allows for complex thought Collaborative and interprofessional	Facilitator skill required High faculty, time, and space costs Students may have different styles and learning needs that are incompatible
Team-based learning	Out-of-class preparation followed by in-class application	Student led Teacher facilitated	Active learning Motivation for learning Allows for complex thought Collaborative and interprofessional Multiple assessments	Facilitator skill required High faculty, time, and space costs Advance student preparation required Students may have different styles and learning needs that are incompatible
Simulation	Practice of scenarios in simulated environments	Teacher led Students active	Hands-on skills practiced Literature from other industries (airlines) supports utility Collaborative and interprofessional	Resource and time expensive Can seem contrived/unrealistic

If assessment truly drives learning, medical educational curricula must be increasingly grounded in the assessment of knowledge and skills acquisition, now defined as abilities (or entrustable professional activities), and composed of individual competencies. Consider a teenager first learning to drive a car. The teen

must be competent in many individual areas, such as knowledge of the laws of the road, and the skills of braking, using turn signals, mirrors, and seatbelts before embarking on this activity. Like supervising a learner performing a technical procedure on a critically ill child, the trust a parent affords a child in independent driving is fluid. The teen may initially receive parental permission for driving around the neighborhood. As the adolescent demonstrates responsible and safe driving conduct, she may gain her parent's trust to drive on the freeway or with friends. Likewise, the graduated ownership a supervising intensivist will allow pediatric learners in performing central line placement will vary according to perceived knowledge and skills, but it is also highly contextual. Allowing an early driver or critical care fellow to navigate new territory is also inexorably tied to how individual parents (or faculty) inherently trust.

We describe evolving methods of assessment and their potential impact on learning in undergraduate, graduate, and continuing medical education within an historical context.

Undergraduate Medical Education

The traditional model of undergraduate medical education experienced in the 20th century and up until this day was largely born out of the Flexner Report.[9] In the early 1900s, 135 unregulated schools without universal requirements for entry or curriculum were functioning, largely as for-profit entities. Abraham Flexner, a prominent American educator, surveyed the scope of medical education; his scathing report led to the closure of all but 31 medical schools. Mergers and university affiliations resulted. The scientific method and the physician as a "social instrument" were championed in Flexner's report.[10] The two-by-two model of basic science (classroom) instruction followed by clinical training was adopted nearly universally, and as a result medical school education remains largely similar across the United States.

The two-by-two model has been questioned.[11] To better prepare physicians for projected needs (increased care coordination, interprofessional collaboration, quality/value-based care), medical schools around the United States are embarking on reform. Additionally, residency program leaders tell us that incoming interns are not residency ready.[12-14] It is unclear if a real decrease in intern readiness exists or if this represents simply anecdotal perception. Nevertheless, the myriad fourth-year medical student and intern "boot camps" common at most institutions at least corroborate these worries. Critical physician workforce concerns as well as mounting student loan burdens compel us to act. Unanticipated challenges such as duty hour restrictions, coding and billing requirements, and the incorporation of the electronic health record into patient care have changed the duties students previously performed, and educators have been slow to adapt.

A desire to evaluate medical student skills (competencies) is a natural path forward. Undergraduate medical education has followed the lead from graduate medical education, adopting the six core competencies for teaching and assessment (Table 23.2). Two ongoing pilots sponsored by the American Association of Medical Colleges (AAMC) address competency-based assessment and progression.

TABLE 23.2

Accreditation Council for Continuing Medical Education (ACGME) Core Competencies

Patient Care Residents must be able to provide patient care that is compassionate, appropriate, and effective for the treatment of health problems and the promotion of health.
Medical Knowledge Residents must be able to demonstrate knowledge about established and evolving biomedical, clinical, and cognate (eg, epidemiologic and social-behavioral) sciences and the application of this knowledge to patient care.
Practice-Based Learning and Improvement Residents must be able to investigate and evaluate their patient care practices, appraise and assimilate scientific evidence, and improve their patient care practices.
Interpersonal and Communication Skills Residents must be able to demonstrate interpersonal and communication skills that result in effective information exchange and teaming with patients, patients' families, and professional associates.
Professionalism Residents must be able to demonstrate a commitment to carrying out professional responsibilities, adherence to ethical principles, and sensitivity to a diverse patient population.
Systems-Based Practice Residents must be able to demonstrate an awareness of and responsiveness to the larger context and system of health care and the ability to effectively call on system resources to provide care that is of optimal value.

From ACGME Common Program Requirements. ACGME approved focused revision effective June 2013, pp. 7-10; https://www.acgme.org/acgmeweb/Portals/0/PFAssets/ProgramRequirements/CPRs2013.pdf.

Exploration of Medical School Progression According to Competency by the American Association of Medical Colleges With the Education in Pediatrics Across the Continuum and Entrustable Professional Activities Pilots

Education in Pediatrics Across the Continuum

In response to adult learning principles and with attention to the costs and rigidity of the traditional undergraduate medical education (UME) time-based model, an

AAMC initiative is testing the feasibility of competency-based medical education with Education in Pediatrics Across the Continuum (EPAC).[15] A pilot group of medical students may advance through medical school as they master skill sets; progression is based on a demonstration of defined outcomes instead of time. In 2013, participating schools began to identify pediatric-leaning medical students to join the cohort. This pilot is currently ongoing, and outcomes are eagerly anticipated.

Entrustable Professional Activities

Residency program directors have been increasingly vocal about their perceptions that medical students are not *residency ready. Boot camps,* which are commonly held as capstone courses during the fourth year of medical school or early in internship, support this concern. The Core Entrustable Professional Activities for Entering Residency give a narrative voice for the progression of medical students to abilities required of a day-one, residency-ready intern. Thirteen entrustable professional activities (EPAs) have been defined with mapped competencies (Table 23.3). Writing orders, formulating a differential diagnosis, collaborating within an interprofessional team, and providing informed consent are examples. The AAMC seeks to determine how EPAs will be taught and assessed. Ten medical schools are currently participating in a pilot to study EPAs in undergraduate medical education.[16] It remains to be seen how program directors will use this information in their decision making when selecting medical students for their training programs.

TABLE 23.3

Core Entrustable Professional Activities for Entering Residency

EPA 1: Gather a history and perform a physical examination
EPA 2: Prioritize a differential diagnosis following a clinical encounter
EPA 3: Recommend and interpret common diagnostic and screening tests
EPA 4: Enter and discuss orders and prescriptions
EPA 5: Document a clinical encounter in the patient record
EPA 6: Provide an oral presentation of a clinical encounter
EPA 7: Form clinical questions and retrieve evidence to advance patient care
EPA 8: Give or receive a patient handover to transition care responsibility
EPA 9: Collaborate as a member of an interprofessional team
EPA 10: Recognize a patient requiring urgent or emergent care and initiate evaluation and management
EPA 11: Obtain informed consent for tests and/or procedures
EPA 12: Perform general procedures of a physician
EPA 13: Identify system failures and contribute to a culture of safety and improvement

Graduate Medical Education

Like undergraduate medical education, today's system of graduate medical education is a 20th-century phenomenon.[17] In the early 1900s, hospitals were primarily a place where one, especially if indigent, went to die. With the advent of technology, procedures, and aseptic technique, hospitals became a place of cures, leading to around-the-clock staffing needs. Specialization ensued and newly graduated MDs desired training in top-notch programs such as those offered by children's hospitals. By the end of World War I, with the advent of accreditation bodies, training programs as we know them today had largely replaced the apprenticeship (or "house pupil") models of the early 20th century. After World War II, increasing numbers of women and racial minorities, who were previously denied entry into the system, were included. The pace of specialization/subspecialization, combined later with federal funding, led to an explosion in the number of graduate medical education (GME) trainees. The passage of Medicare and Medicaid in 1965 allowed for hospitals to bill professional fees for faculty who oversaw the instruction and training of house officers, creating funding mechanisms to pay resident salaries. The resident as "employee" versus "student" remains a critical question today.

The long residency duty hours, historically born at least partially out of staffing needs, have been restricted. This has undeniably changed the landscape of learning. The need to transfer or hand over care has prompted educational reform with programs such as I-PASS.[18] Despite their universal acceptance and requirements for compliance monitoring, it is unclear whether duty hour changes have led to improved educational or patient care outcomes.[19,20]

Graduate Medical Education: Evaluation by Milestones

Building on the competencies, the Pediatric Milestone Project, a partnership between the Accreditation Council for Continuing Medical Education (ACGME) and American Board of Pediatrics, was designed for the evaluation of resident physicians participating in ACGME-accredited residency or fellowship training programs. Milestones are intended to provide a developmental framework for learner assessment. Fig. 23.2 provides an example of one milestone evaluation. Although they are not intended to address all competencies, milestones are anchored contextually in the development of the physician in key elements of the competencies. Milestones are now routinely used in GME evaluations; UME evaluations will likely follow suit.

1. Gathers and synthesizes essential and accurate information to define each patient's clinical problem(s). (PC1)				
Critical deficiencies			**Ready for unsupervised practice**	**Aspirational**
Does not collect accurate historical data Does not use physical exam to confirm history Relies exclusively on documentation of others [?] to generate own database or differential diagnosis Fails to recognize patient's central clinical problems Fails to recognize potentially life threatening problems	Inconsistently able to acquire accurate historical information in an organized fashion Does not perform an appropriately thorough physical exam or misses key physical exam findings Does not seek or is overly reliant on secondary data Inconsistently recognizes patients' central clinical problem or develops limited differential diagnoses	Consistently acquires accurate and relevant histories from patients Seeks and obtains data from secondary sources when needed Consistently performs accurate and appropriately thorough physical exams Uses collected data to define a patient's central clinical problem(s)	Acquires accurate histories from patients in an efficient, prioritized, and hypothesis-driven fashion Performs accurate physical exams that are targeted to the patient's complaints Synthesizes data to generate a prioritized differential diagnosis and problem list Effectively uses history and physical examination skills to minimize the need for further diagnostic testing	Obtains relevant historical subtleties, including sensitive information that informs the differential diagnosis Identifies subtle or unusual physical exam findings Efficiently utilizes all sources of secondary data to inform differential diagnosis Role models and teaches the effective use of history and physical examination skills to minimize the need for further diagnostic testing

Beyond Undergraduate Medical Education and Graduate Medical Education

Continuing Medical Education, Board Certification, and Maintenance of Certification

The speed of medical and technical advance makes it difficult to argue against physicians practicing continuous learning. Continuing medical education is designed to promote the knowledge, skills, and performance of physicians and is managed by the ACGME.[21] Further, continuing medical education requirements are determined and monitored by state licensing boards. In Oregon, for example, the Oregon Medical Board, out of the office of the secretary of state, sets standards and monitors by audit the 30 hours/year of continuing medical education (CME) required by all practicing physicians.[22] Individual institutions, private agencies, and the American Academy of Pediatrics offer CME activities to fulfill these requirements. Additionally, states may require additional education; in Oregon, physicians are required to complete additional pain management education. Traditionally, methods of delivering CME for physicians involve didactic

experiences such as grand rounds or other lecture series. It is reasonable to question whether these experiences are sufficient to drive outcomes, either in physician knowledge, practice, and, most important, patient-centered outcomes. Furthermore, evidence suggests physicians, like all learners, are unreliable self-assessors,[23] highlighting the need for external review to produce and ensure learning outcomes.

Board certification and maintenance of certification complements GME and CME in certifying practitioners in standards of excellence, *which are intended to lead to high-quality health outcomes for their patients*. Accreditation boards such as the American Board of Pediatrics[24] have a duty to the public, ensuring physicians participate in recertification through retesting and maintenance of certification activities. The requirements for pediatric board certification include graduation from medical school, completion of a 3-year ACGME-approved training program, a valid, unrestricted license, and a passing score on the American Board of Pediatrics Certification Examination. Introduced in 2010, the maintenance of certification (MOC) process for pediatricians is a points-based system with four components: part 1, professional standing; part 2, lifelong learning and self-assessment; part 3, cognitive expertise—secure examination; and part 4, performance in practice.

Although medical knowledge may be assessed through standardized testing, it is unclear whether this or other activities for certification truly lead to improved patient outcomes. How can this goal be achieved? Institutions and organizations that create CME programs are actively making connections with MOC requirements.[25] A physician can participate in practice-based improvement activities and receive both CME and MOC credit. To be effective, these experiences must incorporate adult learning principles, with high relevance to the learner, and require active participation. Additionally, they must be authentic on a local level, addressing local problems and opportunities. Organizations can actively incorporate CME/MOC activities into daily workflow for flexible, real-time learning and assessment.

New Methods of Assessment

Educators and those responsible for certification at all levels are currently actively engaged in discussion of new methods and concepts of assessment. There is a growing appreciation for the value in multiple low stakes assessments that include rich narrative feedback[26] and the integration of these assessments into a composite whole. Formative and summative assessment occurs along a spectrum instead of at discrete points in time. Innovations in higher stakes testing assessment are occurring in all phases of the test development cycle, including design and implementation of items and tests (assessment engineering, automated item generation), items and tasks used within the test (game-based assessment, computer-based simulations, use of Internet or key online resources during a test, and alternative text item types such as drag and drop or multiple correct answers), item selection during the test (computer adaptive testing), and delivery of the test (online proctoring versus test center proctoring versus no proctoring). The rapid development of computer and Internet technology makes innovation inevitable, and the resulting change needs to be managed carefully, with an eye to testing validity and reliability as well as test taker approval.

Assessment engineering is a comprehensive model-based view of test development, administration, and scoring. Components include a construct map,

which represents the visual organization of knowledge about a particular problem; task models, which represent the building blocks of the construct map and are specific proficiencies; and templates, which include the information necessary for generating test items. Creation of a test using assessment engineering principles requires significant resources initially to develop the components (construct map, etc.) but decreased time and cost in the long term.[27] Automated item generation (AIG) is a related test development process in which models are developed, variables defined, and test items automatically generated. The Medical Council of Canada has used AIG and found that it reduced the cost to develop items. In addition, AIG items were more difficult and discriminating.[28]

The National Board of Medical Examiners in the Computer Case Simulation portion of the United States Medical Licensing Exam (USMLE), Step 3, has used computer-based simulations for many years. Case simulations can be realistic and are thought to help evaluate competencies that cannot be evaluated by multiple-choice items. Content experts develop the cases, and multiple experts' judgments about various actions are used to develop scoring tools. Although the potential for simulation to allow for assessment of clinical competency exists, it is less reliable (reproducible) than multiple-choice testing. The items are expensive and time consuming to develop, and test security is difficult.[29]

Game-based assessment is newer and has not yet been implemented in large-scale medical assessments, but it shows promise as the technology evolves. Games are developed based on construct maps and provide a means to evaluate students based on their responses to simulated clinical situations. They may offer another way to determine learner proficiency in more complex tasks.[30] As with computer case simulations as used by the USMLE, game-based assessments will require considerable commitment of resources for initial development.

There is considerable interest on the part of test takers to have open Internet or other online resources available during testing (so-called open-book testing). Although open-book testing may be more realistic and it is thought that it allows testing of higher cognitive skills, the data do not show that it drives deeper learning than closed-book tests.[31] Use of the Internet during testing (open-book testing) can help assess how efficiently and effectively the examinee uses the resource as well as the taker's knowledge. Barriers include security, connectivity, and out-of-date reference material.

Online proctoring refers to proctors monitoring an examinee over the Internet using a webcam and includes authentication of the examinee and monitoring of his or her behavior during the examination. Online proctoring became commercially available in 2006, and there are now several companies that provide the service. Benefits include greater convenience, lower cost, and the potential for greater security. Disadvantages include computer technical challenges, inability to deliver some types of testing over the Internet, and the potential perception of lower security.[32] No proctoring with candidate authentication is also an option but is not yet utilized for high-stakes examinations.

Current Controversies, Future Challenges

Time-Based Versus Competency-Based Progression

Individualized curricula and accelerated progress are highly en vogue. Reform is occurring across the country and brings up a debate not unlike what is held between liberal arts universities and vocational training programs around the country. Is a liberal arts education with its broad base necessary for the adaptability students will need when encountering and navigating an unpredictable workplace? Is the hands-on training that readies students more directly with real-world experiences more applicable and practical?[33] Or is there room to ensure transfer of skill (competence) with both?

Medical education reform must address this same conundrum head-on. Brian Hodges describes this conflict comparing "a tea-steeping versus an iDOC model for medical education."[34] The tea-steeping (or time-based) model has been in place and largely unchanged since the Flexner report. Although we encounter learners of varied strengths and weaknesses, the majority of medical students become physicians when they have completed 4 years of education; residency and fellowship programs likewise graduate trainees when their time is up. Consider instead an outcomes-based educational process by which the trainee is produced or manufactured. Can we produce quality physicians more cheaply and effectively by tailoring experiences toward the end product—for example, can we more efficiently manufacture an intensivist? In the end, Hodges argues for a marriage of time-based and outcomes-based training and highlights entrustable professional activities (abilities that translate competency into clinical practice) as a potential way forward.

Although beyond the scope of the chapter, we would be remiss to not mention factors such as the advent of the electronic health record, compensation and billing requirements, and faculty-driven care, which have undeniably affected the learning environment. Students and residents have different opportunities to learn from those available in the past. More opportunities for hands-on care by faculty and closer supervision of learners at all levels most likely are better for individual patients, but they may not provide some of the most powerful learning experiences of past eras. Even documentation experience may be limited: In some settings, students are not permitted to document patient information in the electronic health record, raising questions about their opportunities to write notes and, more important, organize their thoughts into coherent patient assessments and plans. Intensivists and physicians in general must be attuned to environmental and technologic advances, which change practices and the ways they teach, practice, and learn.

Continuing Medical Education and Maintenance of Board Certification

Some practicing physicians believe medical organizations have distinctly misstepped in pursuits to regulate learning activities. Internists have been particularly vocal in their complaints. In a letter to the Internal Medicine Community on February 3, 2015, the American Board of Internal Medicine admitted "they got it wrong" by establishing and requiring impractical and expensive programs physicians found unmeaningful.[35] Some feel the American Board of Pediatrics is similarly out of touch.[36] As recently as May of 2015, the American Board of Pediatrics initiated steps to simplify and expand options for MOC requirements[37] after criticism that its programs were time consuming, confusing, and expensive. This distress highlights

the need for accrediting bodies to return to adult learning principles—if learners do not *care* about the material (relevance), it will not translate into meaningful outcomes, nor will it find acceptability within a discerning group of learners.

Conclusions

Reform is under way in medical education. New methods to encourage competency-based evaluation and active learning are readily visible. Resource utilization, especially faculty time and energy, is a finite and precious commodity. Reform should not be undertaken for the sake of reform, without clearly defined problems that can be addressed and studied for impact. Practitioners must also remember the less tangible aspects of inspiring future physicians to cultivate genuine passion for self-improvement and a thirst for knowledge in the absence of regulation.[38] How can adult learners capitalize on the natural tendencies for playful inquisitiveness so prevalent in early childhood education? How can medical educators empower physicians in training and in practice to best utilize adult learning principles? Medical education involves a group of individuals for whom society compels the practice of lifelong learning. Students and teachers must be equally compelled to get this right.

CHAPTER 24

Public Health Emergencies and Emergency Mass Critical Care

Robert K. Kanter, †, Carl O. Eriksson, Mary A. King

"Keep your eye on the ball."

Bob Kanter, trailblazer for children in the world of disaster medicine

PEARLS

- Public health emergencies (PHEs) can range from limited events that have no effect on critical care needs to catastrophic events that create demand for critical care beyond standard capacity.
- Pediatric intensivists must be engaged with hospital and regional PHE planning and preparedness efforts for all types of PHEs, whether limited in scope or catastrophic.
- The surge capacity continuum that spans *conventional* to *contingency* to *crisis* capacity should be employed during a PHE that requires an increase in critical care capacity.
- Emergency mass critical care (EMCC) is limited, essential critical care during disasters when critical care demand surpasses traditional resources.
- EMCC delivery can improve patient outcomes and lives saved by conserving, optimizing, and better matching critical care resources to critical care demand.

During a public health emergency like a natural disaster or influenza pandemic, a large number of children may need critical care in order to survive. Because pediatric critical care is so highly specialized, and because so few nonpediatric providers are comfortable caring for the sickest children, the pediatric ICU (PICU) represents an essential part of the response to a PHE. During such an event, the hospital incident command system (ICS) provides a leadership framework within and among organizations responding to an emergency, emphasizing flexibility and

scalability, with clear lines of authority and consistent communications. Within this system the PICU will be a critical role.

Planning and preparedness for PHEs can save lives. Unfortunately, critical care providers receive little training in disaster medicine and response and are often underinvolved in hospital disaster preparedness efforts. Recent public health emergencies have exposed a lack of PHE awareness, training, and preparation by critical care providers. The goal of this chapter is to educate the PICU provider in the principles and tools of PHE preparedness and emergency mass critical care (EMCC). Given the disproportionate scarcity of pediatric critical care resources, PICU providers must help to prepare their unit, hospital, and region for the next pediatric PHE. Preparing for pediatric critical care during small, limited, and routine PHEs can also help intensivists better prepare for any future catastrophic PHEs that necessitate EMCC.

PHEs in North America have included terrorist attacks on the New York World Trade Center and the 2013 Boston Marathon, Hurricanes Katrina and Sandy with subsequent flooding of New Orleans and New York City, a catastrophic tornado in Missouri, a major nightclub fire in Rhode Island, an influenza pandemic, and outbreaks of severe acute respiratory syndrome and Ebola. Whether we remember them as disasters or near misses, these emergencies provided important lessons. All-hazard and incident-specific planning and preparedness make a difference. When carried out, public health preparations (including evacuation, shelter, and aggressive infection control) limited major health effects. When critical care was necessary, existing resources were generally adequate to provide standard critical care when needed. However, small differences in circumstances in any of these recent emergencies might have resulted in much larger numbers of adults and children admitted to adult ICUs or PICUs. It is easy to imagine disasters that would overwhelm existing ICU resources, unless intensive care providers prepare to provide critical care in larger PHEs.

Basic Concepts

National Response Framework and Incident Command System

Responses to major public health emergencies are organized within a National Response Framework, as outlined by the federal US Department of Homeland Security.[1] Emergency responses are always coordinated at the most local jurisdictional level possible, usually at the city or county level. Responses to larger disasters need support from adjacent counties, the state, and sometimes the federal level. The hospital ICS[2] provides a leadership framework within and among organizations responding to an emergency. ICS emphasizes flexibility for any type of event, scalability to the size of the event, clear lines of authority, and consistent communications. Disaster plans at every hospital incorporate ICS principles, and PICU preparedness plans must align with these principles in order to most effectively use limited resources and communicate with the hospital and larger community.

Emergency Surge Capacity

Critical care responses to PHEs are scaled according to the size and severity of the emergency (Table 24.1).[3-5] Emergency surges are categorized as (1) minor, (2) moderate, and (3) major. For a sudden-impact event involving minor (up to 20%) increases above usual peak hospital capacity at one or more local hospitals, conventional surge methods would suffice to provide normal standards of critical care to all those who need it. Conventional critical care surge needs are met by canceling elective admissions, quickly discharging all patients who can safely leave the ICU, mobilizing staff, and adding beds, as feasible. Most hospitals have occasional experience with conventional critical care surge responses.

TABLE 24.1

Spectrum of Surge Capacity

Magnitude of Surge	Minor	Moderate	Major
% Increase in capacity	20%	100%	200%
Response	Conventional	Contingency	Crisis
Response strategies	Conserve Substitute	Conserve Substitute Adapt Reuse	Conserve Substitute Adapt Reuse Reallocate

Data from Christian MD, Devereaux A, Dichter JR, et al. Introduction and executive summary: care of the critically ill and injured during pandemics and disasters: CHEST consensus statement. Chest. 2014;146(suppl 4):8S-34S.

Moderate emergency surges result in an increased patient population of between approximately 20% and 100% of usual capacity and require an increased response to most effectively use limited resources. Contingency surge methods include all elements of the conventional response but include additional strategies. Non-PICU patient care areas may be repurposed for ICU-level care. Staff will need to be leveraged, either by changing provider-to-patient ratios or by using non-ICU staff (often in a tiered approach where bedside care is provided by non-ICU providers, who in turn are supervised by ICU providers). Supplies and equipment must be conserved when possible, and some substitutions, adaptations, and reuse may be necessary when safe. The goal of the contingency surge response is to significantly increase capacity while minimally affecting patient care practices, and thorough planning will increase the likelihood that a contingency surge response will adequately meet patient needs after a PHE.

Emergency Mass Critical Care

Emergency mass critical care (EMCC) approaches are required when a large PHE threatens to overwhelm critical care resources, as well as when conventional and contingency surge responses are inadequate to meet the critical care needs of the population. It is recommended that hospitals with a PICU be able to care for up to three times the usual number of critically ill patients for up to 10 days without outside help.[6] In these circumstances, population-based goals will attempt to maximize the number of survivors by providing immediate life-saving interventions to all persons who are likely to benefit from them, while delaying or forgoing other interventions. This represents a change from usual standards of care to crisis

standards of care and should only be implemented if other approaches are inadequate.

Sudden impact events that stress the resources of a community may require the implementation of temporary reactive mass critical care such as has been orchestrated after events like a major fire.[7] A sustained PHE that exceeds resources in a large geographic area may require the sustained implementation of mass critical care. No historical precedents exist for sustained mass critical care. PHE powers are defined on a state-by-state basis,[8] and ICU leaders must be familiar with their own state and hospital incident command process for authorizing EMCC.

EMCC, whether temporary or sustained, should guarantee the following lifesaving interventions that can be performed immediately: (1) mechanical ventilation, (2) fluid resuscitation, (3) vasopressors, (4) antidotes and antibiotics, and (5) analgesia and sedation. Lifesaving EMCC interventions can be extended to much larger than usual numbers of patients by the following approaches (as depicted in Table 24.1): (1) conservation of resources; (2) substitution of equivalent available interventions for scarce or unavailable treatments; (3) adapting nearly equivalent available interventions instead of other scarce or unavailable treatments; (4) reuse of some single-use items; and (5) reallocation of multiuse resources (eg, a mechanical ventilator) from patients not expected to survive in spite of EMCC to patients with a higher likelihood of survival. The degree of deviation from usual practices must be proportional to the gap between patient needs and existing resources, and EMCC should be implemented in an organized way by each hospital's ICS.

Pediatric Critical Care Needs and Resources in a Public Health Emergency

If a PHE affected persons of all ages equally, children aged 0 to 14 years would account for 20% of all patients and those 0 to 19 years old would account for 28%.[9] Younger patients may be more vulnerable to infections, dehydration, toxins, and trauma and are less able to protect themselves in a dangerous environment. Thus children may be overrepresented in a patient population during a PHE.[3] Accidents involving a child-specific activity or violence intentionally targeting children may result in a patient population predominantly made up of children.

Survival rates from high-risk pediatric conditions tend to be better when children receive care at pediatric hospitals.[10-13] The younger the patient, the more age-specific are the treatment requirements. A national survey estimated a PICU peak capacity of 54 beds per million pediatric population.[14] Because normal PICU occupancy exceeds 50%, fewer than 30 vacant PICU beds per million age-specific population are generally available in a region. Because each region may only be served by a single or a few pediatric hospitals, events that disable a pediatric hospital may disproportionately degrade regional pediatric care.

Quantitative models indicate that survival in a PHE would be improved if a pediatric patient surge is distributed to pediatric beds throughout a region, rather than overloading facilities near the scene of an emergency.[15] Appropriate utilization of pediatric hospitals would be promoted by clear identification of pediatric hospitals, although every hospital must be prepared to stabilize and provide initial care for pediatric patients.[16,17] Unfortunately, control of patient distribution may be impossible in a PHE.[18] As a result, all hospitals must be prepared to care for some

children.[19] Even if pediatric regional resources are used optimally, hospital vacancies to accommodate pediatric surges are much more limited than for adult patients.[20,21] Whether or not patients are distributed optimally to hospitals, outcomes from a hypothetical large PHE are likely to improve with EMCC approaches.[15,22] Additionally, using telemedicine for specialized and potentially unreachable resources such as pediatric critical care may significantly extend the reach of pediatric EMCC during a PHE.

Pediatric Disaster Timeline

When the PICU Is Notified of a Sudden-Impact Public Health Emergency

When a sudden-impact PHE is announced, PICU clinical leaders must immediately focus attention on safety of patients and staff. The hospital's ICS is activated. Normal operations continue until other instructions are received. Staff who are already in the hospital report to their normal assigned work area, notifying their supervisor of their arrival. PICU clinical leaders review the hospital disaster plan, including job action sheets, and discuss expectations with the staff. Hospitals and PICUs with robust emergency surge plans will be able to provide more practical and specific guidance to the on-site PICU clinical leadership, highlighting the need for planning before an event occurs. When possible, PICU clinical leaders will be informed about type, number, and arrival time of anticipated patients. However, such information is often unavailable and inaccurate. Patients in the PICU are evaluated for transfer to a lower level of care or discharge home, and scheduled admissions are reviewed for potential cancellation.

Based on the initial assessment, ICU leaders must determine the number of additional patients who could be accommodated with available staff, equipment, supplies, and space while providing the usual standard of care. Additional needs for staff, equipment, and supplies should be communicated through appropriate channels in the ICS. The ICS will direct the response to ensure adequate staff (including assigning and sometimes reassigning staff, as well as asking clinical leaders to call in additional staff when needed), supplies, equipment, and clinical space. As information about the event becomes available, PICU physician and nurse leaders provide incident-specific just-in-time teaching to staff when warranted. Just-in-time teaching is especially important when less experienced supplemental providers are assigned to the PICU.

At all times, clinical leaders must maintain awareness of the environment, operational problems, disaster-related communications, and reactions of staff, patients, and families.

Emergency Department Phase

To provide continuity of patient care and situational awareness, the PICU team must interact closely with the emergency department (ED). Rapidly accommodating patients from the ED or operating room will be essential to allow those areas to continue receiving new patients. In some cases, PICU staff may be temporarily

reassigned to work in the ED, and the critical care team should be familiar with the ED perspective on disaster responses.

Triage

Triage sorts patients to match their needs with available resources. Triage is an evolving process relative to shifting needs and resources. Prehospital field triage and care are beyond the scope of this chapter, but when they are effective, patients who will benefit from ED care are selected. Some mild patients not requiring ED care may have been mistriaged to receive care, and others may arrive at the ED without prehospital assessment. The “worried well” may constitute a large proportion of patients arriving at an ED. Severely ill or injured patients may arrive later than those with less serious conditions in a sudden impact emergency. Triage categories are assigned in the ED by an experienced clinician whose sole role is to act as triage officer. Elements of the triage process may have to be repeated later according to evolving imbalances of patient needs and resources.

Triage in the ED is performed according to the nature of the PHE. When potential contamination of victims by toxins is involved, initial triage outside the hospital first identifies those needing immediate decontamination to protect the patient, staff, and entire hospital facility. Likewise, when a highly transmissible virulent infection is involved, triage prior to entering the ED identifies and isolates potentially infectious patients at the earliest time to avoid exposing staff and other patients. Failures of triage at the early stages of decontamination and infection control may place staff at risk and may have contributed to the infection of two nurses with Ebola virus in a US hospital during the 2014 Ebola outbreak.[23]

Physiologic triage identifies patients needing immediate lifesaving interventions. Physiologic triage tools identify patients in five categories: (1) those needing immediate lifesaving interventions; (2) those who need significant intervention that can be delayed; (3) those needing little or no treatment; (4) those who are so severely ill or injured that survival is unlikely despite major interventions; and (5) those who have already died. Care of patients triaged to group 4, those who are so severely ill or injured that survival is unlikely, must deviate most significantly from usual approaches to intensive care. Because of overall demands on the system, scarce resources must be allocated to other patients who are more likely to survive. Group 4 patients are sometimes referred to as “expectant.” Expectant patients are defined by current resource constraints and physiologic observations. Palliative care is always provided to expectant patients. Also see the discussion of rationing at the end of this chapter.

No single triage tool is always rapid, completely accurate, appropriate for all ages and disorders, and already familiar to all providers.[24] Staff should be familiar with the physiologic triage tool in use locally. Pediatric experts can partner with regional health care coalitions to provide standardized pediatric health care education, such as pediatric triage, among other specialized pediatric topics.[25]

Decontamination

When indicated, decontamination reduces toxic effects for the victim and avoids contamination of staff and the hospital facility. The airway is monitored and

maintained during decontamination. Antidotes are given after cleaning the site of administration. Age-specific issues include hypothermia in infants and behavioral limitations. Warm water may prevent hypothermia. Young children need assistance undressing, while some older children resist undressing and require encouragement and some privacy.[26-28]

Infection Control

For a public health emergency involving a highly virulent transmissible infection, infection control must begin outside the ED entrance and continue without interruption in the hospital while the patient is infectious. Infection control guidelines have been published[29,30] and should be readily available under hospital policies and procedures.

Some emerging infectious agents such as Ebola virus require specific infection control practices, and meticulous attention to infection control is required in order to limit secondary cases. In some cases, this may result in changes to the care made available (eg, for patients with severe Ebola virus disease, emergency cardiopulmonary resuscitation may present an unacceptably high risk of infecting staff members, and institutions may therefore not be able to offer patients these therapies).[31]

Keeping Families Together, Identifying and Tracking Children, Child Safety

Hospital care of children is more efficient, more effective, and less stressful when children are accompanied by a family member or familiar caregiver. This need must be balanced against other triage considerations. Unaccompanied children must be properly identified, tracked, and reunited with their families, requiring proper identification of adult caregivers before releasing children to them. Pediatric safe areas in hospitals with appropriate staff supervision are necessary. Sample child identification and tracking documents have been designed.[19]

Intensive Care Unit Phase

For a sudden impact event in which the ED phase lasts a few hours, the ICU phase may last weeks. On admission to the PICU, a “tertiary survey” is performed to detect injuries and disorders that were overlooked in the rapid primary and secondary survey. For standard interventions, template orders and an abbreviated hospital record may extend the capacity of an overloaded workforce. Every effort must be made to guarantee the essential critical care interventions: mechanical ventilation, fluid resuscitation, vasopressors, antibiotics and antidotes, and sedation and analgesia.

In order to provide essential interventions, some resource-intensive interventions that are ordinarily considered standard in an ICU may have to be delayed or foregone in a mass critical care situation, because standard care would reduce the population who could receive lifesaving care. Interventions that may have to be delayed include invasive hemodynamic monitoring, intracranial pressure monitoring, renal replacement therapy, extracorporeal life support, parenteral

nutrition, and frequent recording of fluid balance and vital signs.[3,32] Clinical decision making may have to be based more often on clinical judgment and less often on laboratory and imaging studies.

PICU Operations in a Gradual-Onset and Sustained Public Health Emergency

Many of the same considerations pertain to sudden-impact and gradual-onset PHEs. However, a gradual onset allows event-specific preparation. Resources can be augmented, and procedures can be developed and practiced. Staff can be trained. Experience in the early phase of the emergency will provide evidence to refine event-specific recommendations. Rapid publication of such experience has provided rapid evolution of management recommendations in recent PHEs such as outbreaks of severe acute respiratory syndrome, H1N1 influenza, and Ebola virus disease.

Space

Patient care space may be adapted by converting single patient spaces to be used by two or three patients. After exhausting PICU space, additional space for EMCC may also be adapted by using intermediate care units, postanesthesia care units, EDs, procedure suites, or non-ICU hospital rooms. Overflow of critically ill adolescents or young adults may be shared between PICUs and adult ICUs. Overflow of young infants or term newborns may be shared by PICUs and neonatal ICUs. Nonhospital facilities should only be used for EMCC if hospitals become unusable.

Personnel

Supplemental providers may include physicians, nurse practitioners, physician assistants, nurses, respiratory therapists, pharmacists, and emergency medical technicians who have skills in non-ICU pediatrics or nonpediatric critical care. Rapid credentialing procedures, just-in-time education, and close supervision by experienced PICU clinicians will promote the role of supplemental providers. Hospitals should expect and plan for a need for significant psychosocial support for patients and providers during and after a PHE.[33]

Mechanical Ventilation

Most hospitals have only a small supply of standard ventilators and circuits in excess of usual ICU capacity. It may be necessary to consider temporary use of transport and anesthesia ventilators and bilevel positive pressure breathing devices. Some pediatric hospitals use a single type of ventilator for patients of all sizes, with appropriate circuits and software algorithms. In other hospitals, ventilators usually used for adults that have high compliance circuits and adult algorithms may have to be adapted for use in infants or small children. When local supplies have been exhausted in a major PHE, adult-focused pediatric-adaptable ventilators and supplies may be accessed through the Strategic National Stockpile.[34] Some difficulties may be encountered. The inspiratory flow or pressure sensor may not be sensitive to an infant's small inspiratory effort. Thus triggering of inspiration may

fail for synchronized intermittent mandatory ventilation, assist control, or pressure support. Likewise, ventilator algorithms to terminate inspiration pressure support may fail in the presence of air leaks around endotracheal tubes. A substantial air leak around an uncuffed endotracheal tube may result in frequent ventilator alarms indicating low pressure or low exhaled tidal volume.

In a volume-controlled mode, adult ventilators may be unable to provide small tidal volumes and inspiratory flow appropriate for a small infant. Pressure-dependent losses of tidal volume in compressible spaces of adult ventilator circuits exaggerate breath-to-breath variation in delivered tidal volume if peak inspiratory pressure varies with patient effort or changing respiratory mechanics. Difficulties in providing small tidal volumes, as well as variation in ventilation due to leaks around uncuffed endotracheal tubes, may be alleviated by using a time-cycled, pressure-limited mode of ventilation. Supplemental providers need considerable assistance in caring for an infant on a ventilator. Maintaining endotracheal tube patency, stabilization, and proper cuff inflation and evaluating episodes of hypoxemia are challenges even for experienced PICU clinicians.

Manual Ventilation

Few hospitals stockpile enough mechanical ventilators to support three times the usual number of ICU patients. The temporary use of manual ventilation with a self-inflatable bag may be considered to meet mass critical care goals; however, this strategy is not without risk. Manual ventilation has been used successfully via tracheostomy tubes for days in a polio epidemic,[35] temporarily for hours via endotracheal tubes in a power failure,[36] and during weather emergencies.[37-39] It provides similar gas exchange compared with mechanical ventilation.[40-42] However, manual ventilation is labor intensive, is tiring to operators, may expose staff to infection risks as a result of close and prolonged bedside contact, and may lead to unnecessary patient risk of inappropriate gas exchange and barotrauma.

Equipment and Supplies

Mass critical care can only be provided if essential equipment and supplies are available on site. Resupply and rental deliveries may be impossible during a PHE. Thus hospitals must balance the benefits of an adequate stockpile against costs of keeping items on site that may never be used. The Task Force on Mass Critical Care[3] has recommended that a hospital first should target a mass critical care capacity of three times the usual maximum ICU capacity for 10 days.

Nonpediatric hospitals must also consider stockpiling for critically ill pediatric patients as transport and/or open pediatric ICU bed spaces may be unavailable. Although it may be possible to carry out many interventions by adapting nearly equivalent equipment and supplies, some adult equipment cannot be adapted to infants and small children. It is essential to stock adequate numbers of resuscitation masks, endotracheal tubes, suction catheters, chest tubes, intravenous catheters, and gastric tubes in pediatric sizes. If cuffed endotracheal tubes are used, it may be possible to cover all pediatric needs with 3.0-, 4.0-, 5.0-, and 6.0-mm cuffed tubes, reducing the need to stock uncuffed tubes in all other sizes. Guidelines for EMCC ventilators have been provided.[3,43]

Medications

In order to extend medication stockpiles in mass critical care, rules should be formulated ahead of time regarding appropriate substitutions, dose and frequency reductions, converting parenteral to enteral administration, restrictive indications, and shelf-life extension.[3] Experience in recent PHEs indicates that large quantities of analgesics and sedatives are essential.[7,44] Weight-based dosing may be simplified to improve efficiency by specifying a limited number of weight range categories. When time constraints make it difficult to weigh patients, length-based estimates of weight may suffice.[45]

Evacuation

ICU providers must be aware of processes to ensure a safe and timely ICU evacuation. Hurricane Sandy demonstrated a lack of ICU evacuation knowledge, processes, and tools.[46] Pediatric patients are especially vulnerable during ICU evacuation as few hospitals can serve as recipient hospitals and few transport agencies are familiar with pediatric critical care transport for hospitalized pediatric patients. Thus PICU evacuation is critically dependent on regional coordination of PICU resources.[47] ICU-evacuation best practices were reviewed in the most recent Mass Critical Care Taskforce and include tools such as ICU evacuation checklists and job action sheets.[48]

Critical Care in Specific Types of Public Health Emergencies

While all-hazard planning prepares for PICU operations across all types of PHEs, some responses must be event specific. These responses are detailed extensively in standard references.[29,49] In addition to general critical care support, event-specific hospital responses and treatments are briefly outlined in Table 24.2. For any type of emergency, clinical interventions also will be necessary for illnesses and injuries that are indirectly related or unrelated to the primary event. These illnesses and injuries include patients hospitalized before the onset of the PHE.

TABLE 24.2

Specific Types of Public Health Emergencies and Event-Specific Management

Type of Event	Infrastructure	Decontamination	Infection Control	Disorders/Event-Specific Interventions
Emerging infectious illness (influenza, SARS) outbreak	Need for negative pressure isolation		Depending on organism, usually a combination of standard, droplet, airborne precautions	Pneumonia, sepsis Antibiotics/antiviral according to organism Antibiotics for bacterial coinfection
Major earthquake	Extensive damage Mass evacuation likely		Standard precautions	Multiple trauma including crush injuries requiring renal replacement therapy
Hurricane	Extensive damage Mass evacuation		Standard precautions	Multiple trauma

	likely			
Nuclear detonation (terrorism)[57,59]	Extensive damage Mass evacuation likely	Radiation Contamination of body orifices, wounds, skin Treatment of life-threatening injuries is the priority	Standard precautions	Multiple trauma, burns, radiation (bone marrow, immunosuppression, gastrointestinal)
Radioactive dispersal bomb (terrorism)[58,59]	Local damage and contamination	Radiation Contamination of body orifices, wounds, skin Treatment of life-threatening injuries is the priority	Standard precautions	Multiple trauma, burns, radiation (bone marrow, immunosuppression, gastrointestinal)
Chemical attack Nerve agent (terrorism)		Essential, must be rapid	Standard precautions	Antidotes (atropine, pralidoxime) Anticonvulsants Bronchodilators
Chemical attack Vesicants/blister agent (terrorism)		Essential, must be rapid	Standard precautions	Chemical burns, potential airway injury
Chemical attack Pulmonary agent such as chlorine, phosgene (terrorism)		Move to fresh air Irrigate eyes, mucous membranes, skin	Standard precautions	Airway and pulmonary edema
Biological attack Anthrax (terrorism)		If known, direct exposure to spores	Standard precautions	Ciprofloxacin Doxycycline
Biological attack Pneumonic plague (terrorism)			Droplet precautions	Streptomycin Gentamycin
Biological attack Smallpox (terrorism)			Standard, contact, and airborne precautions	Vaccination

Rationing

If a PHE overwhelms resources despite EMCC approaches, rationing of resources may be considered. Rationing might occur on a first-come, first-served basis or by selecting patients most likely to survive as a result of brief lifesaving interventions. Such criteria have been suggested for selecting patients for EMCC when needs exceed resources.[3,50] Proposed eligibility criteria include absence of severe chronic conditions, predicted mortality not exceeding an arbitrary upper limit, and improving clinical status on periodic reevaluations. EMCC exclusion criteria have been proposed that apply to both children and adults.[51] These criteria identify patients with low probability of survival and short life expectancy. In pediatrics, however, there is little consensus about, or data to support, which score to use, especially in light of typical PICU mortality of less than 5%.[6] Triage of resources, or rationing, should only occur using a formal hospital system triage policy and/or protocol and should be performed by trained triage officers with critical care training. At present, neither evidence nor consensus of opinion supports rationing, much less a particular rationing strategy.[52,53] For PHE rationing to be a feasible

option, public and professional consensus is a necessary foundation. Only then could states create a legal basis and liability protections.[54]

As recently as during Hurricane Sandy, however, critical care leaders were asked by hospitals to formulate rationing plans during PHEs.[55] At Bellevue Hospital, there was imminent threat of losing all but six power outlets in the entire ICU on the 13th floor. A multidisciplinary clinical committee prioritized patients for those six electrical outlets using the Ontario Guidelines.[56] Fortunately, the generator power was maintained via the now famous "bucket brigade" that shuttled generator fuel up 13 flights of stairs until ICU evacuation could be achieved. Although these critical care triage plans were not implemented, their use was imminent. It is essential that critical care providers are knowledgeable about hospital and regional EMCC triage protocols and prepared for future events despite the lack of current consensus and data.

SECTION II

Cardiovascular System

OUTLINE

CHAPTER 25

Structure and Function of the Heart

V. Ben Sivarajan, Steven M. Schwartz

PEARLS

- The basic form of the human heart and great vessels is complete 8 weeks after conception, after which the structures grow and mature. Recent data show some limited capacity for hyperplasia that persists even into adulthood.
- The parietal pericardium is a stiff membrane that surrounds the heart loosely, separated from the heart by a small amount of lubricating pericardial fluid.
- Immediately after birth, there is a large increase in total body oxygen consumption and cardiac output to approximately twice its later values.
- Although large arteries are regarded as conduits and capillaries as vessels allowing transport of substances to and from the tissues, many substances can move across arterial walls.
- Standard echocardiographic assessments (ejection and shortening fraction) reflect myocardial performance (load-dependent measure) as opposed to true contractility. Assessments of adequacy of ventricular-vascular coupling (adequacy of contractile status with a given preload given the afterload conditions) can be assessed by noninvasive or invasive methods.

Anatomic Development and Structure

Gross Anatomy

The basic form of the human heart and great vessels is complete 8 weeks after conception, after which the structures grow and mature. The ventricular mass enlarges by cellular hyperplasia and hypertrophy; hyperplasia previously assumed to cease after birth has recently been shown by carbon-14 dating to occur at an annual turnover rate of 1% at age 25 years, decreasing to half that value by age 75 years.[1] Increase of ventricular volumes is believed to depend on the increasing flow through each ventricle; diverting flow from a ventricle causes hypoplasia of that ventricle and its associated great artery. Before birth, left and right ventricles have

equal wall thickness. After birth and clamping of the umbilical cord, there is a rise in systemic vascular resistance and a decrease in pulmonary vascular resistance; as a result, the left ventricle becomes thicker than the right ventricle. Left ventricular wall thickness is proportional to the logarithm of age from conception.[2] The ventricular septum is flat in the fetus. After birth, it bulges into the right ventricle and functions like part of the left ventricle. In the embryo, coronary arteries form in the embryonic epicardial tissue[3] and join the aorta to supply flow to the thickening heart muscle, which can no longer get enough blood from sinusoids from the ventricular cavity.

Muscle fibers in the ventricles form a complex helical array. Fibers in the left ventricular midwall are circumferential, parallel to the atrioventricular groove. From this position the fibers twist gradually as they move toward each surface so that at the epicardial surface they are 75 degrees and at the endocardial surface 60 degrees from the circumferential fibers.[4] Some investigators believe that the muscle fiber layers form one continuous sheet that is wrapped around itself like a turban.[5] When the ventricle is dilated, the fiber angles change and become less effective in ejecting blood.[6]

Microscopic Anatomy

The myocardium is a syncytium made of branching fibers, each consisting of bundles of myocytes in series. The myocytes are joined to adjacent myocytes by the intercalated disk, a set of mechanical junctions: adherens junctions with N-cadherin, catenins, and vinculin; desmosomes with desmin, desmoplakin, desmocollin, and desmoglein; and gap junctions with connexins and N-cadherin.[7-9] The gap junctions transmit the electrical impulse from one cell to the next.

Myocyte

The major components of the myocyte are the sarcomeres, which contain the myofibrillar contractile apparatus; the mitochondria, which contain enzymes for energy production; the sarcolemma, which contains the cell envelope and its extensions into the cytoplasm; the sarcoplasmic reticulum; and the cytosol. The numerous proteins in these structures not only play a role in normal function but, if abnormal for genetic or extraneous reasons, contribute to myocardial dysfunction.[10]

Contractile Apparatus

The functional unit is the sarcomere, defined as the structure between two transverse Z lines,[11-13] representing disks that contain proteins such as α-actinin and filamin, which connect the actin and titin filaments of adjacent myocytes. On each side of the Z line is a light zone, the I (isotropic) band, and in the center of the sarcomere are two dark zones, the A (anisotropic) bands, separated by a light H band in the middle of which is a dark thin M band (Fig. 25.1). The I bands contain paired thin filaments of actin coiled in a helix and attached to the Z lines. In humans, cardiac α-actin makes up 80% of the actin in fetuses and neonates, while skeletal α-actin makes up 60% of the total in adults.[14] Two long tropomyosin filaments lie in the grooves between each pair of actin filaments (Fig. 25.2).[15] Every 400 Å, near the crossover points of two actin filaments, is a troponin complex with the following three distinct troponins: (1) troponin T, which binds troponin to tropomyosin; (2) troponin I, which inhibits actin-myosin interaction; and (3) troponin C, which is a high-affinity

calcium receptor. The thin actin filaments overlap with thick myosin filaments at the A bands. These myosin filaments are composed of light and heavy chains. The light chains coil around each other to form the long core of the myosin molecule. The heavy chains form globular myosin heads that project from the sides of the thick filament toward the actin molecules (see Fig. 25.2). A collar of cardiac myosin-binding protein C encircles the thick filaments. Mutations of this protein are a common cause of hypertrophic cardiomyopathy.[16] Between two A bands there is usually a thin, lighter band, the H band, which has myosin but no actin filaments.[13,15]

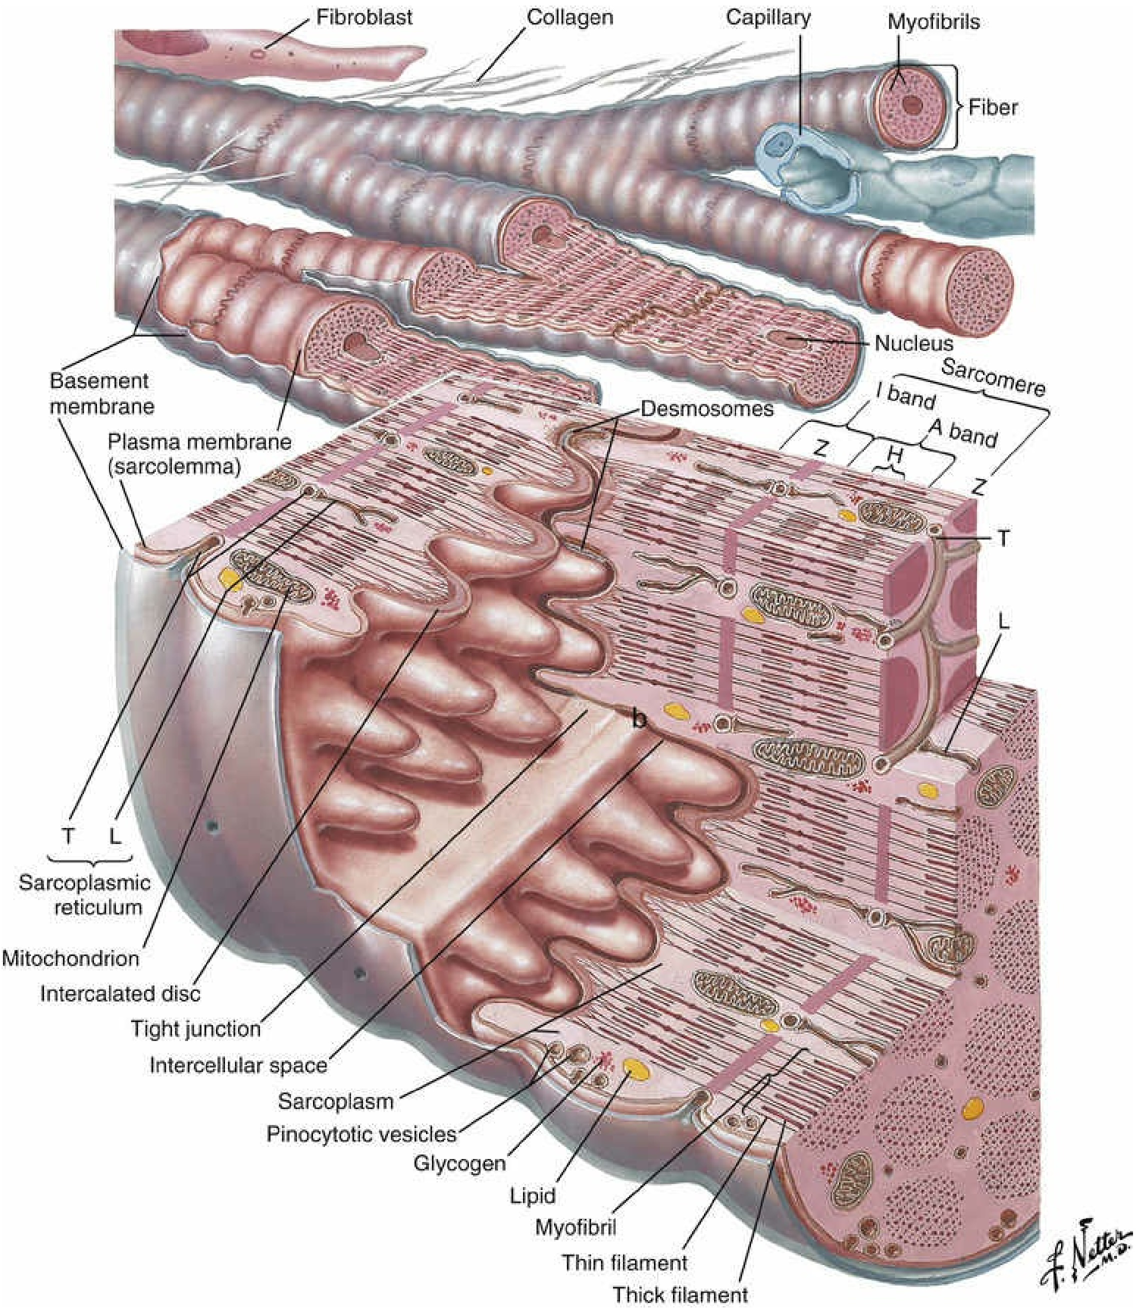

FIG. 25.1 Diagram of cardiac muscle unit showing organization of structural and contractile elements. (Netter illustration from www.netterimages.com.)

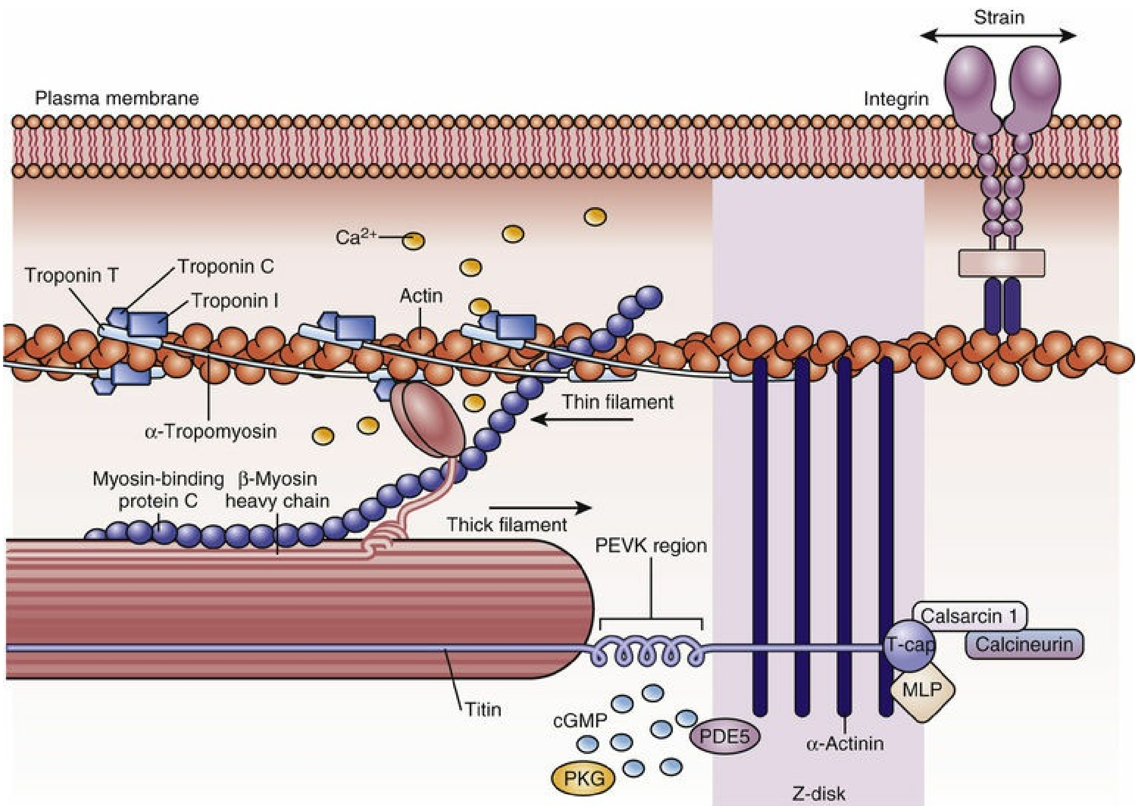

FIG. 25.2 Diagram showing the integration of myofibril contraction (actin-myosin complex formation) to attachments to the Z lines and cytoskeleton via various ultrastructural proteins. (Modified from Mudd JO, Kass DA. Tackling heart failure in the twenty-first century. Nature. 2008;451:919-928.)

Titin, the largest known molecule (molecular weight 3–3.6 MDa, 1-mm long), is the third most abundant fibrillar protein. It extends from the Z band to the M band, has two isoforms, and is the main protein responsible for the elastic behavior of the myocyte.[17] It is essential for sarcomere assembly and for sensing sarcomere length[18] and, with myomesin (not shown in figure), supports the actomyosin filaments (see Fig. 25.2).

Myocytes have fewer myofibrils and more water and cytoplasm before birth than after birth, and the myofibrils do not have the uniformly parallel arrays that they will have after birth.[19]

Sarcolemma and Sarcoplasmic Reticulum

The cell membrane contains receptors, ion channels, pumps, and exchangers. It has indentations overlying the Z bands, and from these indentations small tubules termed *T (for transverse) tubules* penetrate the cell. Abutting against the T tubules are dilated expansions of the sarcoplasmic reticulum (junctional reticulum or cisternae), which join the free sarcoplasmic reticulum, a network of longitudinal tubules inside the cell that surround the thick (myosin) filaments. These tubular systems modulate the entry of calcium to, or its exclusion from, the cytoplasm.[11,19]

The cisternae contain the calcium-binding protein calsequestrin, whereas the longitudinal tubules contain phospholamban and the adenosine triphosphate (ATP)-dependent calcium pump.[19,20] Phospholamban inhibits the affinity of the sarcoplasmic reticulum Ca^{2+}-ATPase (SERCA) pump for calcium, and

phospholamban phosphorylation relieves the inhibition and increases calcium entry with a resulting increase in inotropy.[21-24] In heart failure, phospholamban phosphorylation is decreased by an increase in unphosphorylated calcineurin,[25] leading to decreased SERCA activity.[26,27] A similar decrease in SERCA has been found in sepsis[28] and in some forms of dilated cardiomyopathy.[29] Cisternae store and release activator calcium, whereas longitudinal tubules remove calcium from the cytosol. Calcium release is primarily via the calcium-activated calcium release channel termed the *ryanodine receptor.* Both T tubules and sarcoplasmic reticulum are sparse, undifferentiated, and disorganized early in gestation but increase and differentiate markedly late in gestation and after birth in mammals. Therefore the immature heart depends mainly on extracellular sources for activator calcium,[15,19] partly explaining its marked calcium sensitivity.

Cytoplasm

During development, the proportion of mitochondria in the myocyte increases, particularly at the time of birth, and mitochondria become larger and develop more complex cristae.[19] In the adult, approximately 30% to 40% of the muscle mass is made up of mitochondria. The cytosol contains other calcium-binding proteins[19,30] and other major proteins such as tubulin and desmin.

Cytoskeleton and Extracellular Matrix

For contractile proteins to shorten the whole myocyte, they must be linked to both the cell membrane and extracellular matrix. Longitudinal connections are made via the Z lines, representing disks that contain proteins such as α-actinin and filamin, which connect the actin and titin filaments of adjacent myocytes.[31,32] More lateral connections are made by the extrasarcomeric skeleton. There is an intermyofibrillar cytoskeleton with intermediate filaments, microfilaments, and microtubules.[31,33-35] Desmin intermediate filaments provide a three-dimensional scaffold throughout the extrasarcomeric cytoskeleton and connect longitudinally to adjacent Z disks and laterally to subsarcolemmal costameres.[33,35] Costameres are subsarcolemmal domains located in a periodic pattern, flanking the Z lines and overlying the I bands on the cytoplasmic side of the sarcolemma.[36-40] They contain the focal adhesion-type complex, the spectrin-based complex, and the dystrophin/dystrophin-associated protein complex. The focal adhesion-type complex, made up of cytoplasmic proteins such as vinculin, ankyrin, and talin, connects with cytoskeletal actin filaments with transmembrane proteins such as the dystroglycans and the sarcoglycans.[41-43] Dystrophin is linked to dystroglycan, laminin, and actin. These proteins help to fix sarcomeres to the lateral sarcolemma, stabilize the T-tubular system, and connect the sarcolemma to the extracellular matrix. Voltage-gated sodium channels colocalize with dystrophin, spectrin, ankyrin, and syntrophins. Potassium channels interact with the Z line and intercalated disks. In many of the genetic dilated cardiomyopathies, these proteins are abnormal,[44-46] thereby explaining the abnormal muscle function.

Extracellular collagen plays a major role in cell-cell and cell-vessel interactions and in ventricular stiffness.[47-50] With maturation, more collagen is type III and less is type I.[51] The relationship between sarcomeres and cytoskeleton changes with maturation, perhaps accounting for maturational differences in the resting sarcomere's mean

length in myocytes.[52] In addition, cell adhesion proteins stimulated by growth factors from the myocyte are present in greatest amount in the neonate, decrease with postnatal age, but increase again during hypertrophy.[53,54] Other elements in the extracellular matrix (eg, laminin, fibronectin, and tenascin) play a major role during morphogenesis and during contraction[55] and are important mediators in hypertrophy.

Nerves and Receptors

Adrenergic, muscarinic, and other receptors appear early and are functional even before innervation. Parasympathetic innervation precedes sympathetic innervation in all species.[19,56,57] Innervation is present in the earliest viable human premature infants but may not be fully mature. Innervation is most advanced in species that are most independent immediately after birth.

Cardiac sympathetic nerve fibers come from cervical sympathetic and stellate ganglia. Right sympathetic nerves innervate the right and anterior surfaces of the heart. Left sympathetic nerves innervate the left and posterior surfaces. Vagal nerve fibers descending from medullary centers supply both atria and ventricles and the proximal portion of the bundle of His; the distal part of the bundle of His has only sympathetic nerve supply. Sympathetic and vagal afferents leave the heart and carry information from baroreceptors that respond to high pressures in the ventricles and to lower pressures in the atria, cavae, and pulmonary veins, as well as from chemoreceptors that respond to locally produced substances such as bradykinin and prostaglandin.[58]

Ductus Arteriosus

The ductus arteriosus forms from the embryonic left sixth aortic arch and joins the main pulmonary artery that separates from the truncus arteriosus. The ductus is kept open by a balance between prostaglandin E2 (PGE2) and endothelin-1 (ET-1), both of which are formed in its wall and circulate from other sites. Initially, the ductus is sensitive to the dilating action of PGE2, but, later in gestation, it becomes less sensitive to dilator and more sensitive to constrictor prostaglandins.[59-61] After birth, oxygen reacts with a cytochrome P-450 and causes release of ET-1 (the most powerful ductus constrictor).[62] A switch from dilator to constrictor prostaglandins occurs. In addition, oxygen modulates the function of mitochondrial electron chain transport by increasing the generation of H_2O_2, inhibiting voltage-gated potassium channels in ductus smooth muscle, thereby opening voltage-gated L-type Ca^{2+} channels to cause influx of calcium and ductus constriction.[63-65] These constrictor effects overpower the dilating effect of nitric oxide, which is released from the ductus when oxygen tension rises.[66] The ductus constricts, usually within the first 24 hours and almost invariably within 3 weeks. The lumen then becomes permanently occluded by fibrosis.[61,67]

Physiologic Development and Function

Myocardial Mechanics—Cardiac Sarcomere Function

Excitation-Contraction Coupling

When an electrical impulse reaches cardiac muscle, myocyte membranes depolarize. Extracellular calcium in high concentration at the sarcolemmal membrane and the T tubules enters the cell rapidly. Spread of electrical excitation into the myocyte via the T tubules also causes release of intracellular calcium from the sarcoplasmic reticulum.[11,68,69]

Cytosolic calcium increases from a concentration of 10^{-7} M in diastole to 10^{-5} M in systole. When the calcium that entered the cytosol binds to troponin C, the inhibitory effect of troponin I is antagonized, and a conformational change of troponin and tropomyosin exposes the actin-myosin binding sites.[11,15,68,69] These sites interact with the myosin heads to form the cross-bridges (Fig. 25.3). The myosin heads rotate, generate force, and move the actin filaments, just as oars move a boat through the water. Interaction between actin and myosin pulls the two Z lines toward each other, shortening the muscle and generating force. Increasing intracellular calcium results in greater cross-bridge formation and a greater generated force. Isoforms of the troponins and tropomyosin change during development, but the functional effects of these changes are unknown.[19,70] Troponin I is less sensitive to a fall in pH in the fetus than in the adult, which could be protective in perinatal acidosis.

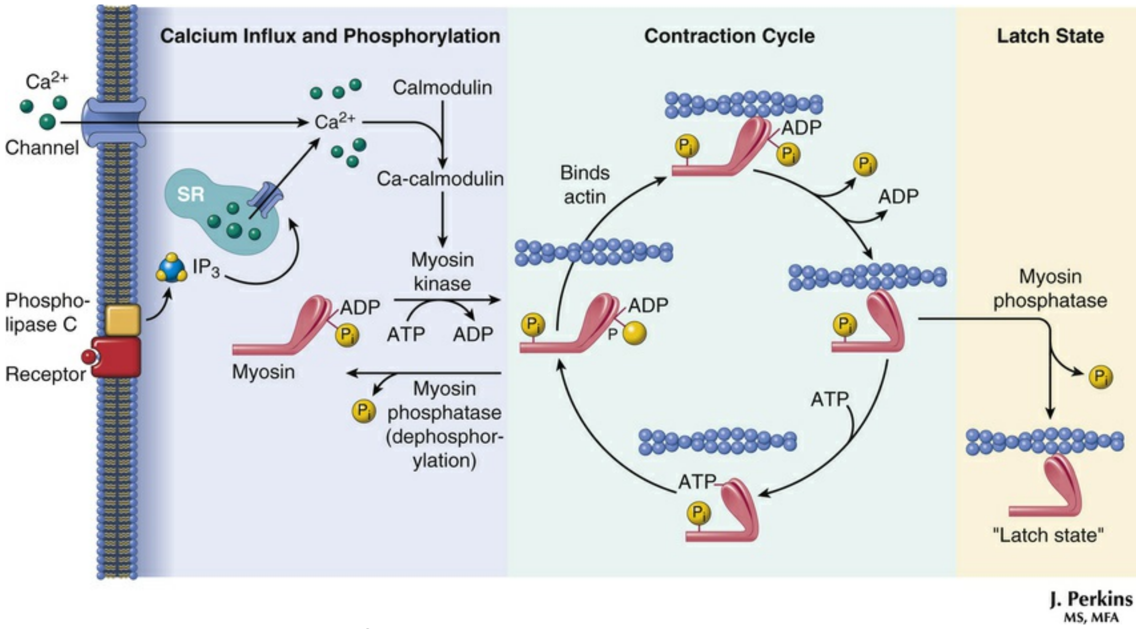

FIG. 25.3 Diagram of cardiomyocyte calcium cycling and adenosine-triphosphate (ATP) utilization during actin-myosin complex formation. (Netter illustration from www.netterimages.com.

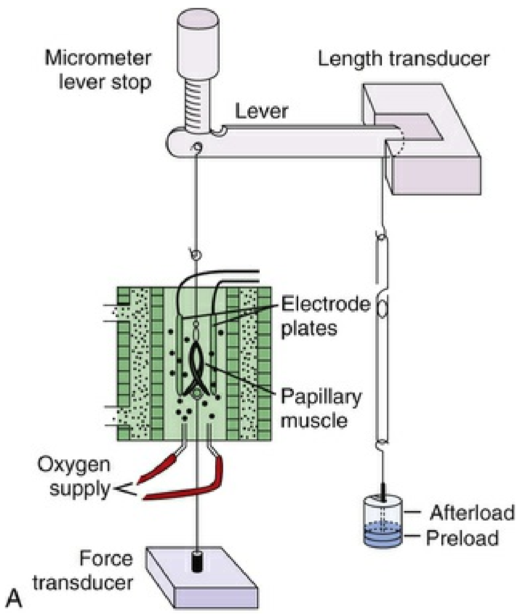
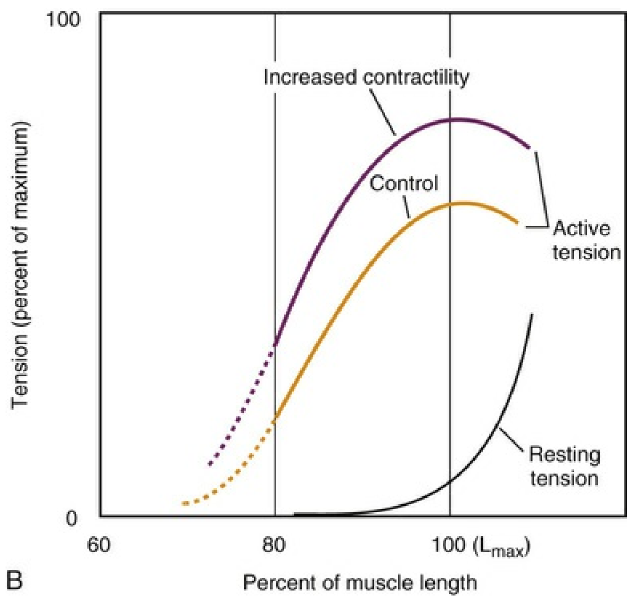
The myosin head contains an ATPase that liberates energy from ATP. The activity of the ATPase determines the velocity of shortening of unloaded muscle by affecting the rate of attachment and detachment of the cross-bridges.[19,71] In most mammalian species, fetal myocardium contains V_3 myosin isoform (having two β heavy chains) with a high ATPase activity rate. In humans and most of the larger mammals, however, almost all ventricular myocardial myosin is V_3 isoform at any age, although human atria contain V_1 myosin isoform.[19]

Sarcomere Length-Tension Relationships

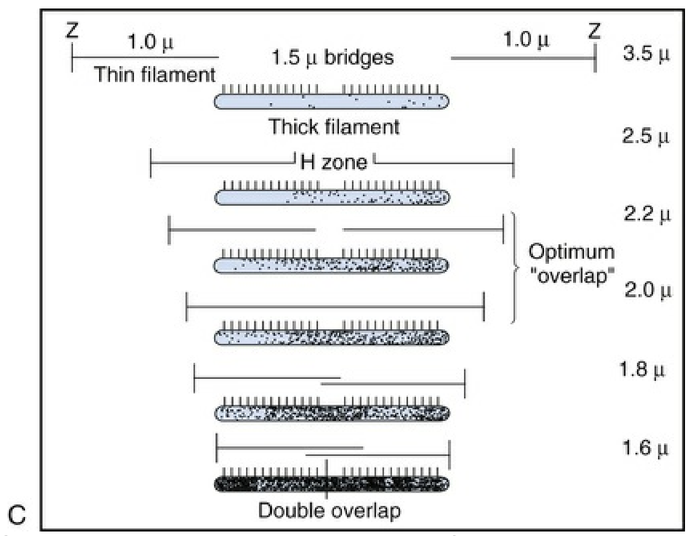
Sarcomere length-tension relationships have been investigated in isolated cardiac muscle strips, usually papillary muscle with its nearly parallel fibers. The muscle strip is placed in a water bath. One end is tied to a lever and the other to a force transducer (Fig. 25.4A). Weights attached to the other end of the lever extend the muscle to any desired length before contraction (preload); excessive stretching is prevented by a stop. Other weights added to the lever after initial length is set affect the muscle only after contraction has started and so are termed the *afterload.* The muscle can be stimulated to contract by an electrical impulse. Instruments for measuring muscle length, sarcomere length by laser diffraction, calcium entry by various fluorescence methods, and a host of other specialized functions can be added.[69,72,73]



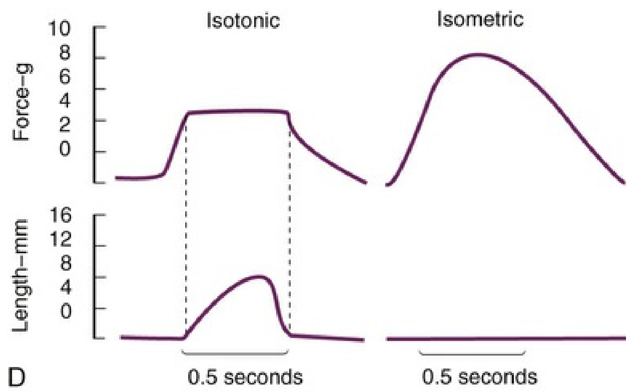
A, Diagram of isolated muscle strip in a water bath and attached to transducers for measuring force and length. Preload is set by the lever stop. (From Parmley WW, Tyberg JV. Determinants of myocardial oxygen consumption. In: Yu PN, Goodwin JF, ed. Progress in Cardiology. Philadelphia: Lea & Febiger; 1976.)



B, Relationship between muscle length and resting tension or active tension at three different contractile levels. (Original drawing by Albert Miller. Redrawn from Sonnenblick EH. Myocardial ultrastructure in the normal and failing heart. In: Braunwald E, ed. The Myocardium: Failure and Infarction. New York: HP Publishing; 1974.)



C, Diagram showing relationships of sarcomere length, positions of the actin and myosin filaments, and contractile force. (Original drawing by Albert Miller. Redrawn from Sonnenblick EH. Myocardial ultrastructure in the normal and failing heart. In: Braunwald E, ed. The Myocardium: Failure and Infarction. New York: HP Publishing; 1974.)



D, Typical length tracings for isotonic *(left)* and isometric *(right)* contractions. The *dashed vertical lines* in the left tracing indicate the portion of contraction in which the muscle shortens against a constant force. (Adapted from Parmley WW, Tyberg JV. Determinants of myocardial oxygen consumption. In: Yu PN, Goodwin JF, eds. Progress in Cardiology. Philadelphia: Lea & Febiger; 1976.)

FIG. 25.4

Stretching relaxed muscle produces an exponential-like increase in passive tension (Fig. 25.4B). This elasticity results mainly from titin.[17,73-75] At very low sarcomere lengths, the actin filaments from each Z line overlap each other. As the sarcomere lengthens, the Z lines move farther apart and a gap appears between the two sets of actin filaments. When the sarcomere reaches a length of approximately 2.2 µm, there is a maximal overlap between actin and myosin filaments[13,69,71] (Fig. 25.4C). At longer muscle and sarcomere lengths, actin and myosin filaments overlap less. The maximal sarcomere length is 3.0 µm. Further elongation of the muscle occurs by slippage of fibers and not by further sarcomere lengthening.[13,69,71]

Active contraction is studied in two ways[72] (Fig. 25.4D). First, muscle is stimulated to contract at different initial muscle lengths but is not allowed to shorten (isometric contraction). At the shortest lengths no force is generated; the muscle remains slack. As sarcomere lengths increase, force is generated and increases to reach a maximum at sarcomere lengths of approximately 2.2 µm. At longer sarcomere lengths, there may even be a decrease in force.[71]

If, at any length, passive tension is subtracted from the tension generated during isometric contraction, the resulting curve demonstrates active tension as a function of length (see Fig. 25.4B).

Second, if afterload is small, the contracting muscle generates an appropriate force and then shortens while force remains constant (isotonic contraction). The rate of shortening is fastest at the onset of shortening, and from it, the velocity of shortening is measured (see Fig. 25.4D). The shortening velocity ranges from zero when the load is so heavy that it prevents shortening to a maximum when the external load is zero[69]; however, true zero loading is impossible because of internal viscosity and elastic forces.[19,71] Increases in cytosolic calcium increase the force generated during contraction but have little influence on the maximal velocity of shortening.

In fetal lambs, the passive tension of muscle strips is abnormally high. Active tension per mm^2 cross-sectional myocyte area at any given afterload is below adult values but is proportional to the reduced number of myofibrils.[19,30,57] Contractile material accounts for approximately 60% of cardiac muscle in adults but only 30% in

fetuses. The extent and velocity of shortening are reduced in fetal heart muscle, but correcting for the amount of contractile machinery suggests the intrinsic performance of fetal and adult actin-myosin filaments is similar.[19] The change from fetal to adult performance seems to occur fairly soon after birth, when the myofibrillar array becomes regular and when the T tubules and the sarcoplasmic reticulum develop into their adult form.[19] For this reason, prematurely born infants (and, to a lesser extent, full-term infants) have a much-reduced ability to tolerate an increase in afterload and are exquisitely sensitive to reductions in serum calcium concentrations.

Myocardial Mechanics—Myocardial Receptors and Responses to Drugs

α_1-Adrenoceptors appear early in gestation and in many species reach their highest density in the neonate.[19,56,76] These developmental changes may be associated with the normal cell hypertrophy that occurs during development. By contrast, β-adrenoreceptors increase progressively with age. Both β_1 and β_2 are present on myocytes.[77,78] In addition, histamine H_2, vasoactive intestinal polypeptide (VIP), adenosine A_1, acetylcholine M_2, and somatostatin receptors have been identified. They act on the myocyte's contractile apparatus through one of two main pathways.

The major pathway involves the membrane-bound receptor–G protein–adenylate cyclase complexes. G proteins include the G_s (stimulatory) and G_i (inhibitory) proteins.[79] In their inactive state, these G proteins include α, β, and γ subunits and guanine diphosphate (GDP). When agonists stimulate β-adrenergic, histamine, or VIP receptors, the G proteins undergo a conformational change. The changes induce the Gs protein to exchange its GDP for guanine triphosphate (GTP) and release the β and γ subunits. The Gs-α-GTP complex interacts with adenylate cyclase to convert ATP to cyclic adenine monophosphate (cAMP), which activates a variety of protein kinases to phosphorylate proteins including voltage-dependent calcium channels, phospholamban, and troponin I. Consequently, calcium entry during depolarization and during uptake of calcium into the sarcoplasmic reticulum storage pool is increased, thus increasing contractility. The Gs-α-GTP complex has intrinsic GTPase activity that converts GTP to GDP. The β and γ subunits rejoin the complex, which now is available for further activation by the receptor. In this way, as long as receptors are occupied by the agonist, the Gs cycle produces increasingly more cAMP, thereby amplifying the stimulatory signal. The Gi protein complex undergoes a similar cycle when adenosine, acetylcholine, or somatostatin receptors are stimulated; however, activating Gi protein reduces cAMP formation and decreases contractility. β_2 Adrenergic receptors also couple to Gi in addition to Gs.[80] Gi in this context is thought to oppose the effects of Gs to some degree, including limitation of the acute positive inotropic response to adrenergic stimulation and offering some protection from apoptosis.[81-83]

Another signal-transducing system in the human heart is the phospholipase C-diacylglycerol-inositol triphosphate pathway, activated by α_1-adrenergic and M_2-muscarinic receptors.[84-86] Occupation of the receptors activates phospholipase C, which cleaves phosphatidylinositol triphosphate in the cell membrane to produce diacylglycerol and inositol triphosphate. The former activates protein C kinase in the

membrane, which may hinder the effects of cAMP. The latter facilitates calcium release from the sarcoplasmic reticulum. This pathway is important in smooth muscle contraction but is of less importance in heart muscle.

In heart failure, the number of β_1-adrenergic and VIP receptors are down-regulated, and β_2-adrenergic receptors are uncoupled from G proteins.[21,77,78,87,88] These changes make the myocardium less responsive to circulating or locally released catecholamines or VIP and play a role in the reduced contractility observed in heart failure. Treating heart failure with β-adrenergic blocking agents has been shown to reverse the receptor changes but has also been associated with improved function of muscle strips in adult patients.[89-92]

Coupling of β-adrenoreceptors is incomplete at birth. Milrinone is an agent that stimulates contractility by inhibiting phosphodiesterases; it bypasses the adenylate cyclase system. Although previously thought to be ineffective in the newborn,[93] a multicenter randomized trial[94] and subsequent widespread use has confirmed its efficacy in the neonatal population.[95,96] Because contractile mechanisms are almost fully developed at birth, the majority of mechanisms controlling contractility (except for changes in the source of calcium) are in place at birth.

Myocardial Mechanics—Integrated Muscle Function

Relationship Between Muscle Strips and Intact Ventricles

Preload stretching a muscle strip is equivalent to end-diastolic fiber length of the intact ventricle. This length can be measured by various devices in animals, but in the intact human ventricle it is best related to end-diastolic diameter or volume. Frequently, end-diastolic pressure has been used interchangeably with end-diastolic volume as an index of preload, but this usage can be misleading if the distensibility of the ventricle changes or if pressure outside the heart (pericardial or intrathoracic) rises.[97-100]

Afterload is more complicated in the intact ventricle. Commonly, aortic systolic pressure is equated with afterload. However, in the muscle strip, afterload represents the force exerted by the muscle during contraction, and pressure and force are not the same.[75,101,102] It is preferable to calculate circumferential wall stress, which at the midwall is a function of ventricular pressure, diameter, and wall thickness. Both peak systolic and end-systolic wall stress can be used to assess ventricular function.

Calculations of wall stress are based on the Laplace relationship:

$$\text{Wall Stress} = \frac{Pr}{2h}$$

where *P* is pressure, *r* is radius of curvature, and *h* is wall thickness. Because the left ventricle is not a regular sphere, particularly in systole, the Laplace formula is an oversimplification.[103] A fairly simple and accurate formula was developed by Grossman and colleagues[104]:

$$\text{Wall stress} = \frac{Pr}{2h}\left[1+\frac{h}{2r}\right]$$

that is, as the Laplace equation modified by the expression in parentheses. Note that if the left ventricle dilates acutely, wall stress rises markedly because *r* gets bigger and *h* gets smaller.

The major findings from studies of muscle strips have been confirmed in intact ventricles. Increasing preload increases the pressure generated by an isolated ventricle that is not allowed to eject, as observed in the past century by Otto Frank. If the ventricle is allowed to eject, then increased preload allows the heart to eject the same stroke volume against an increased afterload or else to eject a greater stroke volume against a constant afterload. This is the Starling component of the Frank-Starling law.[105,106] The mechanism of this response is twofold: (1) lengthening the sarcomere narrows it and places the myosin and actin fibrils closer together for stronger interaction, and (2) increased calcium sensitivity is mediated in some way by titin stretching.[18] If an inotropic drug is given, then contractility increases and, from a given fiber length, greater force of contraction is achieved. This is a phenomenon seen every day in the ICU.

The force-frequency relationship can be determined in intact hearts[107,108] by examining the response of the maximal rate of change of pressure (dP/dt max) in the ventricles after premature beats. The results in intact ventricles and muscle strips are similar. Subsequently, Seed and colleagues[109] applied this technique to humans with normal or abnormal left ventricular function and found an optimal R-R interval of 800 ms. They also examined dP/dt max for two beats given at optimum intervals after the premature stimulus. As expected, the first normal beat after the premature beat was potentiated because the extra calcium introduced into the cytosol by the premature beat was available to potentiate the first beat after the premature stimulus. The second postpremature beat also was potentiated but less so. They used the ratio of the potentiation of these two beats to calculate the fraction of calcium recirculating from one beat to the next. This amount was constant in any one patient but was much less in those with left ventricular dysfunction.

Pressure-Volume Loops

If left ventricular pressure and volume are measured simultaneously, the resulting pressure-volume loop gives information about ventricular function and can be used to assess myocardial contractility in the intact heart.

The modern approach to analyzing these loops is based on the elastance concept of Suga and Sagawa.[110-112] Elastance is the ratio of pressure change to volume change. Consider an isolated ventricle containing a balloon that can be inflated to different volumes. At each volume the ventricle is stimulated to contract and generates a peak systolic pressure (Fig. 25.5A). As volumes increase, so do the peak systolic pressures generated, and the relationship is linear (Frank's law). The line joining the peak pressures intercepts the volume axis at a positive value, termed V_0, that indicates the unstressed volume of the ventricle. The equation for this line is as follows:

$$P_{es} = E_{es}\left(V - V_0\right)$$

where P_{es} is end-systolic pressure, E_{es} is slope of the line, V is the volume of interest and V_0 is unstressed volume. If contractility increases (more calcium enters the cells), the ventricle can generate greater pressures at any given volume, thereby generating a steeper pressure-volume line (higher value of E_{es}; purple line I in Fig. 25-5A). If contractility decreases, the ventricle generates lower pressures at any given volume, and the pressure-volume line is less steep (lower value of E_{es}; blue line D in Fig. 25.5A). E_{es} is also termed E_{max}.

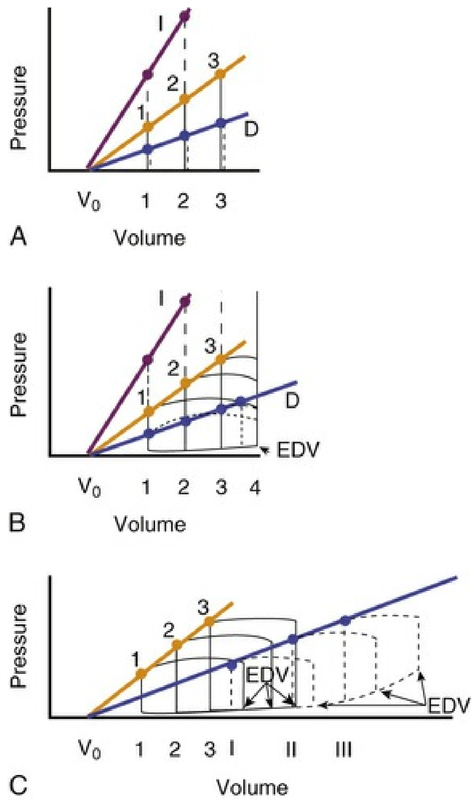


FIG. 25.5 Diagrams illustrating the concept of ventricular elastance. A, Isolated ventricle contracting at volumes 1, 2, and 3, generating corresponding pressures. *Purple line I* indicates results at increased contractility. *Blue line D* indicates results at decreased contractility. V_0, resting (unstressed) volume. B, Ventricular pressure-volume loops achieving end-systolic pressures of 1, 2, and 3 at corresponding volumes. *Purple line I* indicates results at increased contractility, with greater end-systolic pressures at each volume. *Blue line D* indicates results at decreased contractility. From a given end-diastolic volume, either the same ejection fraction is delivered at a lower end-systolic pressure *(dotted line 1)* or the same end-systolic pressure is achieved but at a much smaller stroke volume and ejection fraction *(line 4).* C, When the ventricular end-diastolic volumes *(EDV)* increase as afterload increases, as is normal, then stroke volume can be maintained, even though ejection fraction decreases. If contractility is decreased *(blue line),* then stroke volume can be maintained only with increasing end-diastolic pressures. *1, 2, 3,* end-systolic volumes and pressures at normal contractility. *I, II, III,* end-systolic volumes at decreased contractility.

If the ventricle is allowed to eject, the typical pressure-volume loop shown in Fig. 25.5B is seen. During diastolic filling, volume increases and diastolic pressure rises slightly because of the increase in passive tension. At the end of diastole, isovolumic systole occurs and ventricular pressure rises with no change in volume. When ventricular pressure exceeds aortic pressure, the aortic valve opens, blood is ejected, and ventricular volume decreases. Ejection ends, and pressure falls to diastolic levels as isovolumic relaxation occurs. The pressure and volume reached at the end of systole are those that would have been attained by the isolated ventricle at that same end-systolic volume. In other words, at a given volume, no higher pressure can be generated (loop 1; see Fig. 25.5B). The decrease in volume during ejection is the stroke volume, which, divided by the end-diastolic volume, gives the ejection fraction; normally, ejection fraction is greater than 65%.

If afterload is suddenly increased by raising aortic pressure, the normal heart responds as shown in Fig. 25.5B. In the first beat after the increase, the ventricle has to generate a higher pressure before the aortic valve opens (loop 2). It then ejects but cannot eject a normal stroke volume because that would require higher pressure from the same end-diastolic length (preload). In fact, the end-systolic volume is that which is appropriate for the higher pressure (compare Fig. 25.5A and B). If different afterloads are used, the end-systolic pressure-volume points define a sloping line that is the same as the line obtained in the isolated heart at those same volumes; this is the maximal ventricular elastance (E_{es}) or end-systolic elastance (E_{es}) line. If ventricular contractility increases, then the ventricle can attain higher ejection pressures at any given volume, and the end-systolic pressure-volume points lie on a steeper line that lies above and to the left of the normal line (purple line I in Fig. 25-5B). If ventricular contractility decreases, then the ventricle cannot generate normal pressures at any given end-diastolic volume and the end-systolic pressure-volume line lies below and to the right of the normal line (blue line in Fig. 25.5B). Note from Fig. 25.5B, that, from a given end-diastolic volume, the ventricle with impaired contractility can either eject a normal stroke volume at much reduced pressures or eject at a normal pressure only by reducing its stroke volume drastically (loop 4).

In beats that follow a sudden increase in afterload, the ventricles adjust. Because of the reduced stroke volume in the first beat, the end-systolic volume is larger than normal. During diastole, however, a normal stroke volume enters the ventricle so that end-diastolic volume increases (loop 2 in Fig. 25.5C). In normal ventricles, the increased end-diastolic fiber length causes little increase in diastolic pressure. The pressures during ejection and the end-systolic pressure-volume point are unchanged, but stroke volume and ejection fraction increase. After a few more cycles, a new equilibrium is established (loop 3) in which the ventricle ejects a normal stroke volume at the higher afterload. The ejection fraction, however, is subnormal because although the stroke volume is normal, the end-diastolic volume is increased. The ventricle has adapted to the higher afterload by increasing end-diastolic fiber length, a phenomenon described by Starling and discussed by Ross[101,102] under the term *preload reserve.* If the ventricle has decreased contractility (dashed loops), the same pattern of response occurs but with some important differences. With decreased contractility, the ventricle cannot eject a normal stroke volume from a normal end-diastolic volume. Compensation results in a larger than normal increase in end-diastolic volume, even at normal afterloads. Any increase in afterload causes a further increase in end-diastolic volume, and this increase causes

diastolic pressures to rise to high values that cause pulmonary congestion. The normal preload reserve has been used up in the attempt to eject a reasonable stroke volume against a modestly increased afterload. In more depressed hearts, even normal afterloads cannot be handled by the ventricle without a pathologically raised diastolic pressure in the ventricles or a drastic decrease in stroke volume. Note that in these hearts, because of the relatively flat slope of the maximal ventricular elastance line, a slight reduction of afterload produces a relatively large increase in stroke volume and a relatively large decrease in ventricular end-diastolic volume and pressure. This is one of the mechanisms for cardiac improvement with afterload reduction.

The normal right ventricular (RV) pressure-volume curve is triangular in shape, unlike the more rectangular left ventricular (LV) pressure-volume curve.[113] This difference is accounted for by a relative lack of isovolumic contraction and relaxation times in the RV. The normally low afterload of the RV and the high compliance of the outflow portion of the ventricle allow ejection to begin almost instantaneously after the onset of contraction and proceed through pressure decline so that there is near complete emptying of the ventricle by the end of systole and the ejection time of the RV thus spans the entire period of systole. An important consequence of this relationship is that even small increases in RV afterload begin to make the RV pressure-volume curve begin to resemble the normal LV pressure-volume curve, with isovolumic contraction and relaxation times becoming more prominent.[114] Ejection fraction is reduced, although stroke volume may be maintained due to RV dilation,[115] and the thin-walled RV may handle this new physiology quite poorly.

Assessing Myocardial Contractility

An index of contractility must reflect the ability of the ventricle to perform work independent of changes in preload and afterload. Contractility can perhaps best be defined as the alterations in cardiac function that occur secondary to changes in cytosolic calcium availability or sarcomere sensitivity to calcium. Thus β-adrenergic agonists or phosphodiesterase inhibitors, which increase cytosolic calcium, and thyroxine, which alters myosin ATPase sensitivity to calcium in some species by altering the dominant isoform, are positive inotropic agents. However, quantifying contractility in the intact heart or assessing contractile effects of an intervention is difficult[72] because all indices of contractility are indices of overall performance and are not independent of the other determinants of performance. For example, cardiac output is an excellent index of the systolic performance of the intact ventricle, but it is not a useful index of contractility because of its high sensitivity to preload, afterload, and heart rate. It is convenient to divide methods of assessing contractility into those based on early events in the cardiac cycle (isovolumic phase indices) and those that occur later (ejection phase indices).

Isovolumic Phase Indices

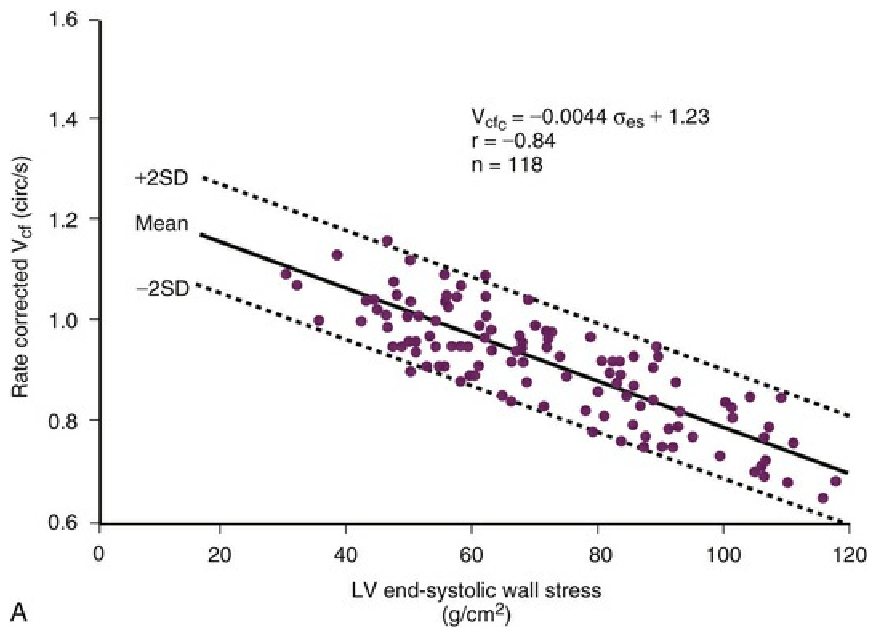
The concept of maximal velocity of contraction against zero load (V_{max}) once was popular, but the complexity of the mechanics of cardiac muscle made it difficult to assess what would have been the true index, namely, V_{max} of the contractile element alone.[116] In practice, too, it is not possible to abolish internal loading of the muscle fiber. Applying this concept to the intact heart was even more difficult.[117]

As a substitute for V_{max}, investigators used dP/dt max (maximal rate of change of ventricular pressure) or dP/dt at a developed ventricular pressure of 40 mm Hg. These values usually are achieved before the aortic valve opens and are relatively unaffected by changes in preload. The index is, however, affected markedly by changes in afterload and so must be used with care when afterloads are very different. This method is more useful for measuring acute changes in contractility than for assessing absolute contractility.

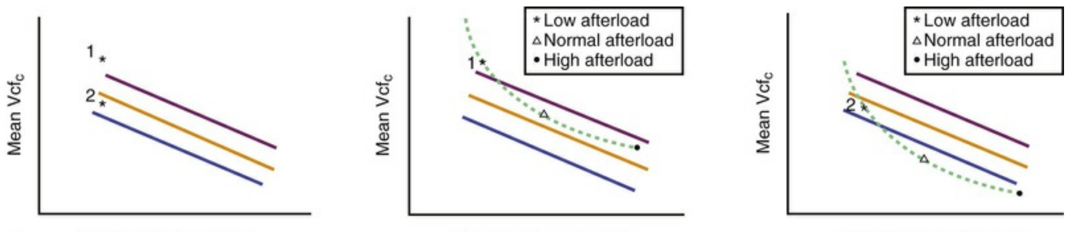
Ejection Phase Indices

The index of contractility most commonly used today is the maximal (end-systolic) ventricular elastance of Suga and Sagawa, which is independent of changes in preload (see previous text). Several different afterloads must be obtained, and either ventricular volumes must be measured or echocardiographic dimensions must be used as substitutes for volumes. The most clear-cut results have been obtained when reflex changes in contractility are prevented, which may explain why the relationship is less well established in conscious than in anesthetized animals.[75,118] Several studies have shown that the maximal elastance line often is alinear and gives a negative intercept on the pressure axis, that is, a negative resting volume.[119,120] To deal with this simply, some investigators use the values of E_{max} in the midrange of pressures.[120]

Ejection fraction and velocity of shortening also provide information about ventricular function. Because these two variables depend on afterload (see Fig. 25.5), it is necessary to adjust for changes in afterload. This adjustment has been made in adults and children[121-126] by providing normal data for the relationship between end-systolic wall stress and either velocity of shortening or ejection fraction (Fig. 25.6). However, the relationship is not linear,[127] so single-point determinations are of little use.



A, Relationship between rate-corrected mean velocity of fiber shortening *(V_{cf})* and left ventricular *(LV)* end-systolic wall stress. (From Colan SD, Borow KM, Neumann A. Left ventricular end-systolic wall stress-velocity of fiber shortening relation: a load-independent index of myocardial contractility. J Am Coll Cardiol. 1984;4:715.)



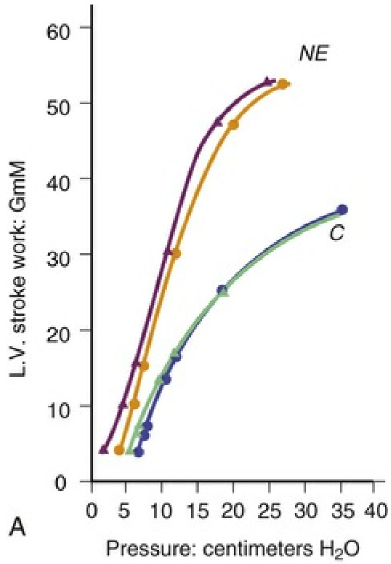
B

B, Possibility of misinterpreting the relationship between mean velocity of fiber shortening and end-systolic wall stress. *Left,* Data point 1 is more than two standard deviations *(SD)* above normal relation (taken from left panel), suggesting increased contractility. Data point 2 is within the normal range, suggesting normal contractility. *Middle,* Alternative explanation for point 1 is that contractile state is normal, but points obtained at very low afterloads follow a hyperbolic, not a linear, relationship. *Right,* Alternative explanation for point 2 is that contractility is decreased, but because of the hyperbolic relationship and the low afterload it appears within the "normal" linear range. (Adapted from Banerjee A, et al. Nonlinearity of the left ventricular end-systolic wall stress-velocity of fiber shortening relation in young pigs: a potential pitfall in its use as a single-beat index of contractility. J Am Coll Cardiol. 1994;23:514.)

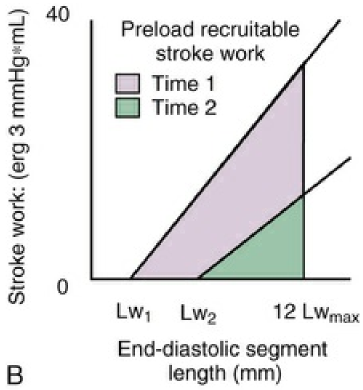
FIG. 25.6

Ventricular Function Curves

Sarnoff and Mitchell[128] introduced the ventricular function curve. They measured LV diastolic pressure and stroke work, then infused fluids and examined the relationship between the two variables (Fig. 25.7A). If contractility increased, the curve shifted up and to the left; at any end-diastolic pressure, a greater stroke work was achieved. If contractility decreased, the curve shifted down and to the right. One problem with this technique, recognized by Sarnoff, was that curvilinearity of the diastolic length-pressure relationship produced an S-shaped curve when relating stroke work to end-diastolic pressure and that techniques for measuring fiber length or ventricular volume were inadequate. In addition, using pressure instead of fiber length or volume may lead to misinterpretations if pericardial or pleural pressures change substantially. Several groups of investigators adapted this function curve to examine the stroke volume to end-diastolic pressure relationship, but this is even less satisfactory because stroke volume is affected by the resulting increases of afterload.



Ventricular function curves. A, Typical function curve relating left ventricular diastolic pressure to left ventricular (external) stroke work. *C,* control state; *NE,* increased contractility resulting from norepinephrine infusion. *Pairs of lines* indicate repeatability of the measurement. (Redrawn from Sarnoff SJ, Mitchell JH. The control of the function of the heart. In: Hamilton WF, Dow P, eds. Handbook of Physiology, Section 2: Circulation, vol 1. Washington, DC: American Physiological Society; 1962.)



B, Preload recruitable stroke work area, in which the area under the curve relating end-diastolic segment length to stroke work is indicated for two different contractile states of the ventricle. Lw_1, Lw_2, intercepts on the x-axis; Lw_{max}, maximal value of *Lw* for the whole experiment. For details, see reference. (Adapted from Glower DD, et al. Quantification of regional myocardial dysfunction after acute ischemic injury. Am J Physiol. 1988;255:H85.)

FIG. 25.7

More recently, the relationship of stroke work to end-diastolic fiber length or ventricular volume has been examined in conscious dogs with autonomic blockade.[105] This relationship, termed *preload recruitable stroke work,* was linear and independent of changes in afterload (Fig. 25.7B). The line intercepted the length or volume axis at values close to the unstressed length or volume, that is, at the length or volume that the ventricle has at zero transmural pressure. Calcium infusion increased the slope of the line without changing the intercept on the length axis. Subsequently, the same group extended this analysis to ischemic ventricles.[129] Depression of ventricular function shifted the stroke work to end-diastolic segment length relationship to the right (increased intercept) and decreased the slope. This concept and the ventricular elastance concept have much in common. Both require measurements of wall force, stroke work, ventricular volume, or minor axis diameter and changing them over a range so that the lines or areas defining these indexes can be obtained.

Pericardial Function

The parietal pericardium is a stiff membrane that surrounds the heart loosely, separated from it by a small amount of lubricating pericardial fluid. Intrapericardial pressure is negative, reflecting the negative intrapleural pressure. On the other hand, the pericardium exerts a surface pressure on the heart that would exist even if all fluid were removed. If the pericardium had holes in it, fluid would leak out and there would be no fluid pressure, but the heart still could be compressed. This surface pressure varies in different regions but, in general, is similar to right atrial pressure.[99,130] As a result, in the usual situation transmural diastolic pressure across the wall of the left ventricle is not the same as left ventricular diastolic ventricular pressure. It can be estimated by subtracting right atrial pressure from LV pressure. The pericardium can restrict dilatation of the LV if there is a tense pericardial effusion (tamponade)[131] or if the ventricles dilate acutely. Thus if the ventricles enlarge because of sudden volume load or sudden myocardial depression, the pericardium becomes tense and restrains further enlargement of the ventricles.[99,100]

In some patients with acute myocardial ischemia, left ventricular diastolic pressure can be greatly increased without much change in ventricular volume because of tension in the pericardium. This mechanism makes it difficult to interpret changes in diastolic pressure-volume relations only in terms of myocardial stiffness.[97,98,130,132,133]

Ventricular Interaction

A closely related mechanism is ventricular interaction.[132] For example, if right ventricular output decreases, a series interaction reduces left ventricular filling and, therefore, LV output. Second, a direct interaction occurs because the left and right ventricles share the ventricular septum and are contained within the same relatively rigid pericardium. Consequently, RV distension, as in acute pulmonary embolism or congestive heart failure, pushes the septum to the left, thereby decreasing LV volume and preload. The resulting decrease in cardiac output should not be taken to indicate LV dysfunction.[99,134,135] Additionally, the LV generates a substantial portion of RV contractility[136] and the decrease in cardiac output that occurs with acute RV failure with an intact pericardium is at least partially attributable to a decrease in LV

performance.[137] Cardiac output can be improved in this situation by opening the pericardium.

The effects of pericardial restraint and ventricular interaction come into play during positive pressure ventilation.[138] With a normal circulation, an increase in intrathoracic pressure will decrease transmural pressures, end-diastolic volumes, and stroke work of both ventricles. However, in the context of the normal circulation, these changes have no observable clinical effects. In congestive heart failure, however, where pericardial restraint regulates total cardiac volume, increased intrathoracic pressure decreases RV transmural pressure, filling, and volume, resulting in increased LV transmural pressure, end-diastolic volume, and stroke work via the Frank-Starling relationship. The ultimate effect of increased intrathoracic pressure in congestive heart failure (from a common intervention such as positive pressure ventilation) is highly dependent on intravascular volume status. In volume-depleted patients, the effects on the right heart will predominate, resulting in further reductions in cardiac output. Adequate volume status, however, will allow the beneficial effects of increased intrathoracic pressure on the LV to dominate, resulting in an increase in cardiac output.

Diastolic Ventricular Function

Diastolic function concerns the rate and extent of ventricular relaxation.[98,139] Many forms of heart disease manifest abnormalities of both systolic and diastolic function, but one or the other form of dysfunction may predominate and determine the type of therapy needed.

Diastolic dysfunction is manifested mainly by increased ventricular diastolic pressure at normal or even low ventricular volume.[139] This can result from increased passive stiffness of the ventricles because of chronic infiltrates (eg, amyloid), myocardial scars, constrictive pericarditis, or diffuse myocardial fibrosis. It also can result from impaired relaxation. Normally, relaxation of ventricular muscle in diastole is rapid and associated with rapid release of calcium bound to troponin and its subsequent uptake by the sarcoplasmic reticulum. Removal of calcium allows actin-myosin cross-bridges to dissociate and the sarcomeres to lengthen, thereby permitting the ventricle to dilate. Any decrease in calcium removal because of abnormalities in major contractile proteins or transport processes decreases the rate and extent of relaxation.[73,140,141] Ischemia is one major factor that impairs calcium metabolism and diastolic ventricular function, but many other forms of heart disease have similar effects.[26,29,108,142] Clinically, diastolic function is assessed by relating end-diastolic pressure and volume, by observing the rate of ventricular filling by angiography or by Doppler studies of the mitral valve inflow, by measuring the peak rate of fall of ventricular pressure (−dP/dt max), or by calculating the time constant of the fall in ventricular pressure.

Neural Control of the Heart

The heart can function without any cardiac nerves, for example, after cardiac transplantation. However, the response to exercise in these denervated hearts is slow and due to increases in circulating catecholamines and the rise in body temperature. In intact animals and humans, β-adrenoreceptor blockade blunts the heart rate increase with exercise and abolishes inotropic response, as judged by the increase in

dP/dt max.[143]

Studies of the neural control of the heart must consider the basal level of sympathetic and parasympathetic tone.[143] In conscious animals, resting sympathetic tone is low and resting parasympathetic tone is high. Therefore sympathetic blockade has little effect on heart rate and myocardial contractility, but parasympathetic blockade causes marked tachycardia. On the other hand, many anesthetics depress the sympathetic nervous system, leading to impaired contractility and bradycardia. Postoperatively, patients often have high circulating catecholamine concentrations, and the effects on myocardial function depend on the balance of catecholamine concentrations, stimulation of the sympathetic nervous system by pain, and extent of myocardial depression caused by the drugs used for sedation.

The carotid and aortic baroreceptors respond to changes in arterial blood pressure. If basal sympathetic tone is low, as is normal, then inhibiting sympathetic tone by raising aortic pressure has little effect on myocardial contractility. On the other hand, lowering arterial pressure causes a reflex increase in sympathetic tone, with increases in heart rate and contractility. Baroreceptor sensitivity increases throughout gestation in fetal lambs[144] but may decrease after birth.[145] Also in fetal lambs, denervating the baroreceptors did not alter mean arterial blood pressure or heart rate but did increase the variability of pressure and heart rate. Similar increased variability of pressures but not of heart rate occurred in adult sheep.[146] Denervation in the fetuses in the same study also decreased peripheral resistance.

Carotid and aortic chemoreceptors are stimulated by low P_{O_2}, high P_{CO_2}, and low pH, but the changes have to be marked, and even then the increase in myocardial contractility is modest. The fetus seems to be less sensitive than the adult to chemoreceptor stimulation.[147] The bradycardia that accompanies severe hypoxemia results from vagal stimulation. During exercise or hemorrhage, plasma catecholamines increase markedly, but the inotropic responses are different. With exercise, dP/dt max increases by as much as fourfold, the peripheral vascular bed is dilated, and cardiac output increases, whereas with hemorrhage, dP/dt max increases by only 30% to 50%, cardiac output falls, and most vascular beds vasoconstrict. Thus the pattern of sympathetic neural stimulation rather than the circulating catecholamine concentrations determines how the heart responds to these stimuli.

Vagal effects on the heart are shown most prominently by changes in heart rate, but their effects on myocardial contractility depend on the existing level of sympathetic tone. Vagal stimulation has little effect on myocardial contractility given little sympathetic tone but markedly reduces the inotropic effects of increases in circulating catecholamines or sympathetic nerve stimulation. Conversely, blockade of muscarinic receptors can intensify the myocardial contractile response to sympathetic stimulation.

Cardiac Output

Cardiac output in the fetus is determined mainly by heart rate because of a limited capacity to increase stroke volume. This limitation results partly from decreased diastolic distensibility and partly from positive extracardiac pressures.[148] Consequently, fetal bradycardia is detrimental to blood flow and oxygen delivery.

The fetal heart, however, can respond to increased preload (Starling's law) with increased stroke volume, provided there is no concomitant increase in afterload.[149] Usually, infusion of fluid into an animal causes arterial pressure to rise, and the increased afterload tends to inhibit the increase in stroke volume that would otherwise occur.[149-151] Immediately after birth, there is a large increase in total body oxygen consumption and cardiac output to about twice its later values (per unit body size).[152]

This increase has been related to an increase in adrenergic receptors stimulated by fetal thyroid hormones.[153] In addition, because at birth approximately 80% of the infant's hemoglobin is in the form of fetal hemoglobin, the reduced ability of this hemoglobin to unload oxygen at the tissue level compels the infant to have a higher cardiac output than the infant will have 4 to 6 weeks later.[152] Therefore the neonate has limited cardiac output reserve and the heart has near-maximal contractility.[154,155] These features make the neonate unusually susceptible to diseases that impair cardiac function. The Frank-Starling mechanism, however, is intact at this time.[156] Evidence indicates β-adrenoreceptor stimulation helps the neonatal ventricle adapt to volume loads.[157] Thus β-adrenoreceptor blockade might be expected to be much more harmful in the neonate than in the older person with minimal sympathetic tone.

Myocardial Metabolism: Normal Myocardial Energy Metabolism

Basic Metabolic Processes

Basal metabolic processes can be studied by measuring oxygen uptake, production of heat, or utilization of high-energy phosphates. In isolated papillary muscle, most of the oxygen consumed is used in generating force (internal work), approximately 15% is used in shortening (external work), approximately 20% is used for basal metabolic processes (protein synthesis, sarcolemmal Na-K transport), and approximately 10% is used for the activity of Na/K-ATPase and Ca-ATPase.[158-160] Similar conclusions can be drawn from studies of whole hearts.[161]

The myocardium has a brisk rate of metabolism, consuming approximately 8 to 10 mL oxygen/100 g muscle/min under basal conditions. Potassium-induced cardioplegia can reduce myocardial oxygen consumption, but “resting” cardiac muscle still consumes more than five times as much oxygen as does resting skeletal muscle. During maximal exercise, the myocardium may consume as much as 60 to 80 mL oxygen/100 g muscle/min.[162]

Cardiac energy is generated by oxidizing substrates to carbon dioxide and water. During this process, energy is both used and stored, and most of the stored energy is in the form of ATP. When needed, ATP breaks down to adenosine diphosphate (ADP) or adenosine monophosphate (AMP) and releases energy for contractile or transport processes.[163] The substrates for energy production can be glucose, lactate, or fatty acids.[164] In a mixture, the fatty acids are preferred over the others, and an increase in plasma fatty acid concentrations, as in fasting or sympathetic stimulation, suppresses oxidation of carbohydrates by the heart.[55,164] Therefore lactate consumption or extraction cannot be used as an accurate guide to cardiac metabolism unless the concentration of the fatty acids is evaluated at the same

time.[165] ATP is usually generated by oxidative phosphorylation. Various transport systems move the substrates into the mitochondria for oxidation by the tricarboxylic cycle. Other transport systems move the ATP out of mitochondria into the cytosol, where they can break down and supply energy. The ATP is replenished by transfer of a high-energy phosphate moiety from creatine phosphate to ADP, mediated by the enzyme creatine kinase.[163,166] When oxygen supply is restricted, ATP can be generated by anaerobic glycolysis, an inefficient but useful temporary pathway. Furthermore, products of glycolysis, if they accumulate, inhibit key enzymes and interfere with further ATP production. Therefore the myocardium is unable to build an oxygen debt without further depressing energy production and, hence, contractility. Oxidative metabolism is so important to the heart that more than 30% of the mass of the myocardium is mitochondria.[158]

Fetal lamb ventricles have the same oxygen consumption per unit mass as the adult left ventricle. Because fetal oxygen content is lower than that in the adult, however, myocardial blood flow per unit mass is about twice as high in the fetus as in the adult.[167,168] Oxidative capacity is relatively lower, and glycogen stores and glycolytic flux are relatively higher in the fetal heart. This condition may explain why the immature heart is more resistant to hypoxemia than is the adult heart, provided an adequate supply of glucose is available for glycolysis. The main substrates used by the fetal heart are glucose, lactate, and pyruvate, although ketones, amino acids, and short- and medium-chain fatty acids also can provide energy.[169] After birth, long-chain fatty acids become the predominant substrates. For these reasons, prolonged severe hypoglycemia can seriously depress cardiac function in the neonate but is unlikely to do so in the older person.

L-Carnitine is essential for fatty acid transport across the mitochondrial membrane. Most of the body's carnitine is produced endogenously when protein degradation releases trimethyl-lysine, which is transformed into carnitine. Carnitine is present in red meats and dairy products (including breast milk), but only small amounts are present in vegetable products. It can be absorbed by the intestine, is not broken down in the body, and is excreted by the kidney.

In all except young infants, the preferential source of energy for myocardial function comes from the β-oxidation of long-chain fatty acids. After fatty acids enter the cell, they are activated to fatty acid (or acyl) coenzyme A (CoA) compounds by palmitoyl-CoA synthetase, then linked by carnitine palmitoyl transferase I to carnitine to form acylcarnitines, thus releasing CoA. The acylcarnitines cross the mitochondrial membrane, and at the inner surface of the membrane another enzyme, carnitine palmitoyl transferase II, transfers the fatty acids back to CoA. The fatty acids can now undergo β-oxidation with the production of ATP. These enzymes also help transport acylcarnitine esters of CoA out of the mitochondria. These esters are toxic in high concentrations. Fetuses and neonates have decreased activity of carnitine palmitoyl transferase and palmitoyl-CoA synthetase, so glucose, lactate, and short-chain fatty acids are the preferred myocardial energy substrates at this age.[19,170]

Endogenous carnitine production is usually sufficient for growth, but plasma (and tissue) carnitine concentrations may decrease after 1 month of parenteral nutrition without carnitine supplements. Energy demands increase when renal excretion of carnitine increases in conditions of burns, sepsis, starvation, or after surgery; with excess excretion in Fanconi syndrome; with drugs such as valproic acid,

pivampicillin, and pivmecillinam, which bind to carnitine and are excreted; with decreased production during chronic hemodialysis; and with cirrhosis of the liver.[171,172] Carnitine concentrations may be low in very premature infants.[173] Ischemia of heart or skeletal muscle depletes carnitine in the affected tissues, as does chronic congestive heart failure.[174,175] Most cases of severe carnitine deficiency in children, however, result from inherited defects in intermediary metabolism.[176]

Carnitine deficiency may produce acute or chronic syndromes, including a Reye syndrome–like encephalopathy, hypoglycemia, myopathy, cardiomyopathy, and failure to thrive. Once the diagnosis is established, treatment is with a diet high in carbohydrates and short-chain fatty acids, plus carnitine supplements by mouth (25–300 mg/kg/day) or even intravenously if needed. Patients with congestive heart failure who do not show overt evidence of carnitine deficiency may improve after taking carnitine supplements.[175]

Determinants of Myocardial Oxygen Consumption

In 1958, Sarnoff and Mitchell[128] reported that pressure work by the heart consumed more oxygen than did volume work and found a good correlation between the area under the LV pressure curve in systole (termed the tension-time index) and left ventricular oxygen consumption. Subsequently, others found that peak wall tension (or stress) was a better predictor of left ventricular oxygen consumption.[177-180] It is important to take account of wall thickness and ventricular dimensions in estimating myocardial oxygen consumption, which is why the tension-time index, which ignores wall stress, is not a good predictor. Increases of contractility or heart rate also increase myocardial oxygen consumption, but because they decrease ventricular size and thus wall stress, increased oxygen consumption is not as great as would be expected from studies in muscle strips.[181]

Stroke volume is an added predictor of myocardial oxygen consumption.[12,182-185] The approaches used include examining the area within the pressure-flow loop. This approach has been extended by Suga and colleagues,[112,186-191] who concluded that the best predictor of LV oxygen consumption was the area in the pressure-volume loop plus the area representing end-systolic pressure energy (Fig. 25.8). By subtracting the contributions of basal myocardial metabolism, they were able to show that the oxygen consumption–pressure-volume area (PVA) relationship was independent of contractile state. Further studies by these investigators showed that PVA-independent oxygen consumption was a function of contractility, defined by E_{max}. Certain interventions, for example, acidosis, made the slope of this relation between PVA-independent V_{O_2} to E_{max} steeper, that is, they decreased the efficiency of the system.

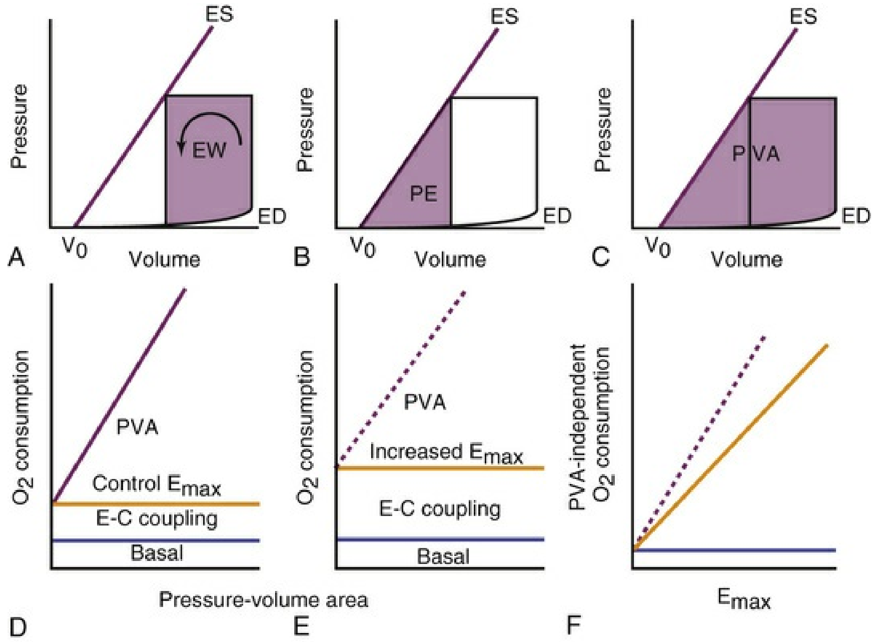


FIG. 25.8 Relationship of myocardial oxygen consumption to the pressure volume area (PVA). A, Ventricular pressure-volume loop with pressure plotted on the ordinate and volume on the abscissa. *Arrow* shows the direction of inscription of the loop. *ED,* end-diastolic pressure-volume line; *ES,* line of end-systolic pressure-volume points (end-systolic elastance); *EW,* area representing external mechanical work; V_0, unstressed ventricular volume. B, *Shaded area* to the left of the pressure-volume loop in the pressure-volume diagram represents potential energy (PE). C, Total area (PVA) is the sum of the external mechanical work area (EW) and the potential energy area (PE). D, PVA is linearly proportional to oxygen consumption, but some oxygen consumption is independent of PVA. The PVA-independent oxygen consumption shown below the *upper horizontal line* results from excitation-contraction (E-C) coupling and basal oxygen consumption. E, When contractility is increased, as indicated by the increased value for E_{max}, the relationship between PVA and oxygen consumption is unchanged, but PVA-independent oxygen consumption increases. F, Relationship between E_{max} and PVA-independent oxygen consumption is linear. With myocardial depression, the slope of this relationship is steeper *(dashed line).* Thus for any value of E_{max}, PVA-independent oxygen consumption is increased so that myocardial efficiency is reduced. (Data from references 61, 62, 125-127.)

Because oxidizing fats uses up more oxygen than does oxidizing carbohydrates, theoretically more oxygen should be used per unit of work when burning fatty acids. Though not consistently demonstrated, there are a few good studies of this phenomenon.[166]

Myocardial Oxygen Demand-Supply Relationship

One way of assessing myocardial oxygen demand is to note that it is roughly proportional to the ventricular systolic pressure generated and the duration of systole, that is, to the area under the real-time pressure curve of the ventricle in systole: the systolic pressure-time index (SPTI).[192,193] SPTI is dramatically influenced by cardiac afterload; for instance, aortic stenosis raises SPTI (at constant stroke

volume). The correlation between SPTI and myocardial oxygen demand is imperfect because it does not take into account wall stress, which involves radius and wall thickness, or contractility.[194]

Because left ventricular myocardial perfusion is restricted to diastole (see Chapter 26), myocardial oxygen supply is proportional to both duration of diastole and myocardial perfusion pressure in diastole. In general, diastolic myocardial perfusion pressure can be represented graphically as the difference between superimposed aortic and left ventricular pressure curves. The area between these curves, from the instant of aortic valve closure in diastole to reopening of the aortic valve in systole, has been termed the *diastolic pressure-time index* (DPTI) and is proportional to subendocardial blood flow. When multiplied by arterial oxygen content, this index correlates with subendocardial oxygen supply.[195]

The ratio DPTI × Arterial oxygen content/SPTI (Fig. 25.9) is a fair indicator of myocardial oxygen balance. At critical levels, subendocardial ischemia occurs.[192,193] This ratio is worsened by tachycardia, which shortens diastole and the duration of myocardial perfusion; by elevation of end-diastolic pressures in the ventricles; or by elevation of coronary sinus pressure. It is adversely affected by low aortic diastolic pressure (as in shock, aortic valve insufficiency, or other large diastolic runoff lesions) and by elevated ventricular systolic pressure (as in aortic stenosis, systemic hypertension, or pulmonary hypertension). The ratio is favorably affected by balloon aortic counterpulsation, which elevates aortic diastolic pressure and reduces systolic afterload. Given the imperfect nature of this ratio, too much emphasis should not be placed on any given value, but two points are clear: (1) A fall in the ratio in any patient moves that patient toward a supply-to-demand imbalance and (2) any ratio less than the 8.9 that typifies normal subjects likely indicates myocardial ischemia.[196]

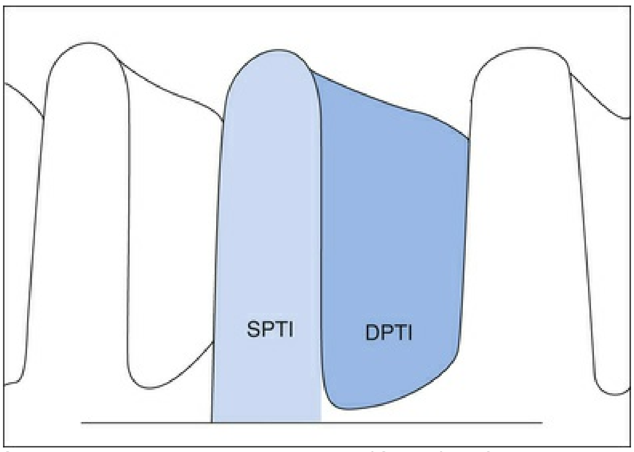

FIG. 25.9 Systolic pressure time index (SPTI) reflects myocardial work and oxygen demand. Diastolic pressure time index (DPTI) reflects myocardial blood flow. (Adapted from Fuhrman BP. Regional circulation. In: Fuhrman BP, Shoemaker WC, eds. Critical Care: State of the Art, vol 10. Fullerton, CA: Society of Critical Care Medicine; 1989.)

Effects of Myocardial Ischemia on Cardiac Function and Metabolism

Ischemia indicates a flow that is inadequate to supply the demand for oxygen by an

organ or tissue; it also implies reduced clearance of metabolites.[197,198] The second part of the definition is what distinguishes ischemia from hypoxemia, in which there is a normal flow with a decreased oxygen delivery. Because the heart cannot sustain an oxygen debt, inadequate oxygen supply rapidly decreases the energy supply to the muscle cells, which cease to contract normally. If a branch of the left coronary artery is severely narrowed or occluded acutely, within 5 to 15 seconds the myocardium supplied by that branch stops contracting, turns blue, and bulges and thins during each systole. If the acute ischemia is global, that is, all coronary arteries have similar reductions in oxygen supply, then the subendocardial muscle becomes ischemic first because this muscle has the lowest coronary flow reserve. Subendocardial function is selectively decreased.[199-201] Global cardiac contractility decreases. Cardiac pump function is impaired, but survival is possible. More extensive global ischemia leads to death. Chronic imbalance of oxygen supply and demand leads to death of the affected muscle cells, producing either a localized infarct or diffuse, perhaps patchy, subendocardial fibrosis as occurs commonly with severe aortic stenosis, cyanotic heart disease, or dilated cardiomyopathy.

Temporary imbalance of supply and demand leads to two patterns of response, depending on the duration of the ischemia. If a branch coronary artery is occluded for 15 to 30 minutes and then the occlusion is removed, flow returns to normal rapidly, but the muscle may not contract normally for many hours. Some biochemical changes that occurred take many hours to reverse. This phenomenon is known as *reperfusion injury* or *stunning*.[202-205] It should be distinguished from the “no reflow” phenomenon in which, after a longer occlusion, release of the occlusion is followed by incomplete restoration of flow because of myocardial edema, cell swelling, plugging by neutrophils, and endothelial damage. Stunning may occur after prolonged cardiopulmonary bypass surgery and may account for some of the cardiac depression that often is observed in the early recovery period.[206,207]

Chronic ischemia of moderate severity causes myocardial hibernation, an adaptive response that leads to metabolic down-regulation and reduction of flow without extensive cell death.[208-211] Regional function is reduced, but restoration of flow leads to functional recovery. This phenomenon is best known from studies of coronary artery disease but can be present in some children with normal coronary arteries and subendocardial ischemia.

Many biochemical changes occur when the heart becomes ischemic and which are the primary causes of the dysfunction is not always clear. As soon as oxygen supply is cut off, all components of the mitochondrial electron chain become reduced because of the absence of the final electron acceptor. Nicotinamide adenine dinucleotide (NAD) is reduced to NADH within 2 seconds after the onset of sudden ischemia.[212] Glycogenolysis increases rapidly, thereby helping to supply ATP, but then is progressively inhibited by increasing concentrations of hydrogen ion, NADH, and lactate. (This inhibition is less marked with pure hypoxemia because the associated high flows help to wash out these inhibitory metabolites.) The stores of high-energy phosphates become depleted. First creatine phosphate decreases and then ATP concentrations fall. For example, after sudden arterial occlusion, creatine phosphate is almost completely depleted within 3 minutes, and ATP is reduced to 35% of control concentration within 15 minutes. ATP is degraded to ADP and AMP, which then is deaminated to adenosine. Adenosine in turn is rapidly broken down to inosine and hypoxanthine. Because of these changes, the nucleotide pool of cardiac

muscle is depleted so that even after flow is restored, a long time is required before normal high-energy stores are replenished. Furthermore, during ischemia, xanthine dehydrogenase in the tissues is converted to xanthine oxidase, which catalyzes the conversion of hypoxanthine to xanthine and superoxide radicals. These in turn can be converted by superoxide dismutase into hydrogen peroxide, which can be converted by catalase to produce highly reactive hydroxyl radicals. These free radicals can react with lipids in the cell membranes and cause lipid peroxidation, which produces several toxic and arrhythmogenic substances and impairs the functions of the cell membrane.[212] Oxygen-derived free radicals can be introduced by activation of neutrophils by the damaged endothelium and by the formation of peroxynitriles from nitric oxide.

Accompanying these changes are accumulations of hydrogen ions, lactate, and many other catabolites. These entities create an osmotic load within the cells, with resultant swelling of the cells and the mitochondria. The cell and mitochondrial membranes become impaired, and myoglobin and enzymes such as creatine kinase leak out of the cell, as do essential ions such as magnesium and potassium. Free calcium may accumulate in the cytosol (because of loss of chelating agents) and the mitochondria, particularly during reperfusion, and this calcium load may be highly detrimental to cell function. Finally, ischemia is associated with decreased myocardial carnitine concentrations, defective transport of long-chain fatty acids into the mitochondria, and accumulation of toxic acylcarnitine esters of CoA. These changes further delay the recovery of energy production and muscle contraction.

Systemic Vasculature

General Anatomy

The large arteries are elastic. Their media contain concentric lamellae of perforated elastic tubes cross-linked by transverse collagen (type III) and smooth muscle.[47,213] When smooth muscle contracts, the wall becomes stiffer. Smaller arteries have fewer lamellae. The media are bounded by the external and internal elastic laminae, beyond which are the adventitia with nerves and vasa vasorum and the intima with sparse fibrous tissue and a metabolically active endothelium, respectively. Arterioles have no lamellae and only a thin media with circular or spiral smooth muscle; the only elastic tissue is in the inner and outer elastic laminae. Capillaries are thin walled and nonmuscular, ideal for transport of materials into and from the tissues; however, they contain pericytes that have myosin, actin, and tropomyosin and so might have some contractile function. Veins have medial muscle but thinner walls relative to lumen diameter than do arteries. Their endothelium may have different properties. The numerous extracellular matrix components are reviewed by Buga and Ignarro.[214] The developmental aspects of blood vessels are reviewed by Stenmark and Weisen.[215]

Physiologic Mechanisms

General Features

Although large arteries are regarded as conduits and capillaries as vessels allowing transport of substances to and from the tissues, many substances can move across arterial walls. Oxygen and carbon dioxide can diffuse across arteriolar walls, and

lipoproteins can penetrate the walls of large arteries. Whether atheromatous deposits form in arteries depends on the balance of the amount of lipoprotein that enters and leaves the arterial wall. This balance depends on the concentration and chemical nature of lipoproteins and the action of components of the wall, such as glycosaminoglycans, in binding altered lipoprotein molecules and preventing their transit through the wall.

Arteriolar tone controls peripheral resistance and, with cardiac output, determines blood pressure and regional flow. Regions of the circulation may differ markedly in their patterns of vascular regulation. A potent stimulus for increased vascular resistance in one region of the circulation may have a different effect in another. For example, during hemorrhagic shock, flow is maintained to heart and brain but is reduced to muscle, kidneys, and gut. Venous and venular tone, together with diuretic and antidiuretic factors, determine blood volume and venous pressure.

The two active components of the systemic circulation are the medial smooth muscle and the endothelium. They both have receptors for innumerable agonists and antagonists that diffuse from autonomic nerve endings, circulate from remote regions, or are produced locally. The smooth muscle is responsible for vasoconstriction or vasodilatation. The vascular endothelium is one of the metabolic powerhouses of the body and has several major functions:

1. Endothelial cells play important roles in the response to injury by causing leukocyte adhesion and extravasation, mediated by cell adhesion molecules such as selectins, cadherins, and integrins.[215,216]

2. They are intimately bound up with coagulation[215,217] by virtue of the production of procoagulant (eg, platelet-activating factor [PAF], von Willebrand factor, fibronectin, and factors V and X) and anticoagulant factors (eg, heparan, dermatan sulfate, thrombomodulin, ectonucleotidase) and by the production of nitric oxide and PGI_2, which inhibit platelet aggregation and degranulation.

3. They regulate capillary permeability by producing ET-1 (increase) or PGE1 (decrease) and respond with increased plasma leakage to substances such as bradykinin, histamine, thrombin, oxygen radicals, and PAF.[218]

4. They regulate smooth muscle contraction in response to shear stress, in keeping with an overriding principle that shear rate must be kept constant within narrow limits to prevent endothelial damage.[219] In general, most of the vascular resistance resides in microvessels smaller than 150 μm in diameter,[220] which are subject to the controls discussed here.

Any increase in local organ flow resulting from a decrease in resistance in these microvessels increases shear stress in the larger upstream arteries. This increase is sensed by endothelial integrins,[221] which set off a cascade of responses that relax smooth muscle by activating Ca^{2+}-sensitive K^+ channels and hyperpolarizing the endothelial cell membrane and by releasing acetylcholine, nitric oxide, PGI_2, ATP, and substance P.[215,222] A chronic increase in shear stress activates the nuclear factor-κB transcription complex and induces a number of early response genes.[215,222]

Control of Vascular Tone

In general, regional circulations regulate their flow so that they obtain required amounts of oxygen and nutrients. Any or all of the mechanisms discussed may be invoked. Vasomotor tone is strongly influenced by several mechanisms: (1) innervation and neural processes, (2) circulating endocrine and neuroendocrine mediators, (3) blood gas composition, (4) local metabolic products, (5) endothelial-derived factors, and (6) myogenic processes.

Receptors responsive to neural products (norepinephrine, acetylcholine, neuropeptides) are found throughout the circulation. Nevertheless, innervation and receptor distributions are organ specific, which allows rapid, patterned, coordinated redistribution of blood flow and an orchestrated response to hypoxia, changes in posture, and hemorrhage. Although these receptors respond to circulating agonists (including angiotensin II and adrenal epinephrine) and to those liberated locally, they are generally associated with innervation by autonomic nerves. In general, presynaptic α-adrenergic stimulation causes norepinephrine release and vasocontriction. β-Adrenergic stimulation generally causes vasodilatation. Cholinergic stimulation (whether sympathetic or parasympathetic) generally causes vasodilatation.

In all organs, sensory and efferent nerve endings contain nonadrenergic, noncholinergic (NANC) peptides, for example, neuropeptide Y, VIP, calcitonin gene-related peptide (CGRP), and substance P.[116,223-234] Neuropeptide Y is colocalized and released with norepinephrine,[235] and VIP is colocalized with acetylcholine and released upon stimulation of vagal nerve endings. Most of these peptides except neuropeptide Y are vasodilatory, and they help modulate blood pressure and regional flows. Substance P and CGRP are released when sensory nerves are stimulated by capsaicin, thus accounting for the flushing that accompanies the eating of hot peppers. (Many neuropeptides also occur throughout the central nervous system, where they may play roles in cardiovascular regulation.)

Humoral regulators of vascular tone and blood volume include angiotensin, adrenomedullin, aldosterone, arginine vasopressin (AVP), bradykinin, histamine, serotonin, thyroxine, natriuretic peptides, and various reproductive hormones. Most of these regulators have both direct effects and secondary effects, which tend to be organ specific or regional. They tend to have altered concentrations in hypertension, congestive heart failure, or shock, and their antagonists are used in therapy. Some agents, such as histamine, serotonin, and thyroxine, probably affect peripheral resistance only in abnormal states and are not physiologic regulators.

Angiotensin plays a special role in the homeostasis of blood pressure. Its concentration increases in hemorrhagic or hypovolemic shock, following increased renal production of renin that produces angiotensin I from angiotensinogen. Angiotensin I is converted to active angiotensin II by angiotensin-converting enzyme (ACE) in the endothelium, especially in the pulmonary vessels. However, angiotensin II is also produced locally in the heart and vessel walls by renin that enters from the blood and perhaps by other local proteases.[236,237] It causes generalized vasoconstriction in both systemic and pulmonary circulations, but locally it stimulates the release of vasodilating prostaglandins in the lung and kidney. Angiotensin II, via angiotensin I receptors, plays a role in cardiac and smooth muscle cell hypertrophy. In excess, it results in cardiac inflammation, fibrosis, and apoptosis.[238-241]

Adrenomedullin, originally found in pheochromocytomas, is produced in many

normal cell types including endothelium. Among its many actions are long-lasting vasodilatation and diuresis.[242,243] It shares homologous sequences with CGRP, calcitonin, and amylin.[244] Its release may be stimulated by ET-1. It may play a role in treating heart failure.[245]

Aldosterone, known primarily for its effect on sodium excretion and potassium retention, has indirect central effects on blood pressure.[246-248] Its concentration increases when renin release is stimulated. In patients with congestive heart failure, its decreased breakdown in the liver accounts for high blood concentrations, which are harmful to the heart and blood vessels. Inhibition of aldosterone by spironolactone may have great clinical value.[247,249,250]

AVP, which is released from the axonal terminals of magnocellular neurons in the hypothalamus, causes vasoconstriction by stimulating VP_1 receptors. However, at low concentrations, AVP dilates coronary, cerebral, and pulmonary vessels. It is an antidiuretic hormone that acts on VP_2 receptors in the renal collecting ducts.[251] Its concentration is low in septic shock,[119] with ventricular arrhythmias, and after cardiac surgery[252] but is increased in myocardial and hemorrhagic shock, congestive heart failure, and cirrhosis of the liver.[106,251,253] Selective AVP antagonists promote free water excretion without concomitant electrolyte excretion[253-256] and are useful in treating fluid overload in patients with congestive heart failure, cirrhosis of the liver, and the syndrome of inappropriate antidiuretic hormone secretion without causing electrolyte imbalance.

Bradykinin is a potent pulmonary and systemic vasodilator released locally by the action of proteolytic enzymes on kallikrein after tissue injury.[257-260] Bradykinin is metabolized by kininase II, which is the same as ACE, so ACE inhibitors not only reduce angiotensin II production but also increase bradykinin concentrations. Bradykinin also causes endothelial cell release of tissue-type plasminogen activator.[261]

Histamine, released by mast cells in response to injury, is a potent vasodilator in most regions of the circulation but causes vasoconstriction in the lung. It also increases endothelial permeability.[262] No evidence indicates histamine plays a part in normal vasoregulation.

The natriuretic peptides are released from the heart when it is distended in congestive heart failure. They cause vasodilatation and increased diuresis. A-natriopeptide (mainly from atria) and B-natriopeptide (from ventricles) are released from myocardial cells, and C-natriopeptide is released from cardiac endothelium.[262-266] A recombinant B-natriopeptide (nesiritide) was initially shown to be safe and potentially more effective than dobutamine in treating acute severe congestive heart failure.[263-266] This is currently being tested in a large multinational randomized controlled trial (ASCEND-HF).[267] These natriopeptides and the kinins are broken down by neutral endopeptidase. Inhibition of this breakdown combined with inhibition of ACE by vasopeptidase inhibitors (eg, omapatrilat) greatly augments vasodilatation.[268-273]

Serotonin probably acts mainly in the central nervous system, but peripherally it can act on S_1 receptors to produce vasodilatation and on S_2 receptors to cause vasoconstriction. It also augments the action of other vasoconstrictors.[271,272]

Tissue levels of oxygen and carbon dioxide reflect adequacy of perfusion and oxygen delivery. These blood gases are potent determinants of regional blood flow

and have effects that differ among regions of the circulation. They also have a more general effect mediated by carotid chemoreceptors.

Local metabolic regulation of vasomotor tone provides an ideal homeostatic mechanism whereby metabolic demand can directly influence perfusion. For instance, adenosine, which accumulates locally when tissue metabolism is high and tissue oxygenation is marginal, causes pronounced vasodilatation in the coronary, striated muscle, splanchnic, and cerebral circulations. Cerebral autoregulation has been suggested to take advantage of local metabolite production as an indicator of adequacy of blood flow. According to the argument, when perfusion pressure falls, cerebral blood flow might decline but for local accumulation of vasodilating metabolites. The perivascular concentration of these metabolites is restored to normal as flow rises, washing out the metabolites. Potassium is released from muscle in response to increased work, ischemia, and hypoxia.[273] Hypokalemia causes vasoconstriction.[274,275] Hyperkalemia, within the physiologic range, causes vasodilatation by stimulating K_{ir} channels.[276-278] Many of the agents previously discussed are produced locally and are effective as circulating hormones. At least four different types of potassium channels are present on arterial smooth muscle cells[278]: voltage-activated channels (K_v), calcium-activated channels (BK_{Ca}), inward rectifiers (K_{ir}), and ATP-dependent channels (K_{ATP}). These channels are activated by vasodilators. As a result, the cells hyperpolarize, voltage-dependent calcium channels close, intracellular calcium concentrations decrease, and vasodilatation results.[278] Pharmacologic vasodilators, such as cromakalim, pinacidil, and diazoxide, directly activate K_{ATP} channels, as do endogenous vasodilators such as CGRP, VIP, prostacyclin, and adenosine.[278] Inhibitors of K_{ATP} channels, such as glibenclamide, cause vasoconstriction.

The endothelial lining of blood vessels plays a prominent role in the regulation of vascular tone.[279] In addition to its roles in the elaboration of vasoactive eicosanoids[280] and in the metabolism of angiotensin, the endothelium secretes several other categories of vasoactive substances, including adrenomedullin (discussed previously), nitric oxide, endothelial cell hyperpolarizing factor, and endothelins.

Endothelium-derived relaxing factor (EDRF) has been identified as nitric oxide.[281] Nitric oxide is a potent vasodilator released from endothelium after stimulation and accounts for some or all of the activity generally ascribed to other agonists. For instance, acetylcholine causes constriction of vessels stripped of their intima and causes dilatation only in the presence of the vascular endothelium.[282] Adenosine, prostacyclin, and epinephrine dilate vessels stripped of their endothelium. Bradykinin, substance P, thrombin, and potassium cause only endothelium-dependent relaxation. Nitric oxide is also released from endothelium when flow increases, an example of positive feedback. Nitric oxide increases smooth muscle soluble guanylate cyclase activity, raises muscle cyclic GMP, and thereby relaxes vascular smooth muscle. In addition to EDRF, endothelial-derived hyperpolarizing factors, which are probably epoxyeicosatrienoic acids and hydrogen peroxide, are now thought to play major roles. The hydrogen peroxide is produced by the action of superoxide dismutase on superoxide anions that are generated by the metabolism of ATP.[282]

The vascular endothelium elaborates the endothelins (ET-1, ET-2, ET-3), a family of compounds that is vasoactive, structurally related peptides. ET-1 is the most

potent vasoconstrictor known. It also promotes mitogenesis and stimulates the renin-angiotensin-aldosterone system and the release of vasopressin and atrial natriuretic peptide.[247,283-286] These peptides act on one of two receptor subtypes: ET_A and ET_B. ET_A is located mainly on vascular smooth muscle cells and is responsible for mediating vasoconstriction and cell proliferation. ET_B is present predominantly on endothelial cells and mediates vasorelaxation, as well as ET-1 clearance. Endothelins cause local vasoconstriction or vasodilatation, depending on dose and location in the circulation.[287] Individual endothelins occur in low levels in the plasma, generally below their vasoactive thresholds. This finding suggests they are primarily effective at the local site of release. Even at these levels, however, they may potentiate the effects of other vasoconstrictors such as norepinephrine and serotonin.[288] Endothelin antagonists, such as bosentan, now are being used, specifically in the setting of pulmonary arterial hypertension.[289,290]

Myogenic responses of vessels are changes in smooth muscle tone in response to stretch or increased transmural pressure. An increase in inflow pressure causes a rise in vessel wall tension and transmural pressure[291] that causes localized vasoconstriction. The reverse occurs when inflow pressure falls. The mechanisms of this response are complex. There is probably initial sensing by surface integrins,[292] followed by activation of cation channels with calcium entry.[293] In some way, protein kinase C, MAP kinases, and Rho kinase are also involved.[294-296]

As expected, a complex interplay exists among myogenic, flow-mediated, and metabolic regulation of vessel tone.[297] The relative importance of these mechanisms likely varies in different vascular beds.

Autoregulation

In all organs, when inflow pressure is suddenly raised or lowered while oxygen consumption remains constant, flow rises or falls transiently but then returns to the earlier value. The phenomenon is termed *autoregulation*. Myogenic tonic response is partly responsible for this phenomenon, but it is not the only mechanism. Some investigators believe tissues have oxygen sensors that respond to transient increases or decreases in oxygen supply.[298-300] Others believe the process is mediated by greater or lesser release of nitric oxide carried to the tissues by hemoglobin in the form of S-nitrosohemoglobin or by ATP release by the red blood cell.[300-305] Carbon monoxide produced by the action of hemoxygenase in endothelium and smooth muscle may play a regulatory role.[306-313]

CHAPTER 26

Regional Peripheral Circulation

Peter Oishi, Julien I. Hoffman, Bradley P. Fuhrman, Jeffrey R. Fineman

PEARLS

- When delivering critical care, one must understand the specific properties that characterize the various regional circulations because therapies that benefit one region may be detrimental to another.
- Vascular tone is influenced by (1) innervation and neural processes, (2) circulating endocrine and neuroendocrine mediators, (3) local metabolic products, (4) blood gas composition, (5) endothelial-derived factors, and (6) myogenic processes.
- The transition from the fetal pulmonary circulation to the postnatal pulmonary circulation is marked by a dramatic fall in pulmonary vascular resistance and rise in pulmonary blood flow. The failure to successfully make this transition is integral to a number of neonatal and infant diseases.
- An important feature unique to the cerebral circulation is the presence of a blood-brain barrier. As a result, the cerebral vasculature responds differently from other vascular beds to humoral stimuli.
- Regulation of myocardial perfusion is tailored to match regional myocardial oxygen supply to demand over the widest possible range of cardiac workload. Increases in myocardial oxygen demand must be met by increases in myocardial blood flow.
- Critically ill patients are at risk for impaired splanchnic blood flow that can impair the two chief functions of the gastrointestinal system: (1) digestion and absorption of nutrients and (2) maintenance of a barrier to the translocation of enteric antigens. Splanchnic ischemia is associated with increased morbidity and mortality in critically ill patients.
- Although renal blood flow remains constant over a wide range of renal artery perfusion pressures, urinary flow rate varies as a function of renal perfusion pressure.

General Features

General Anatomy

Blood vessels comprise several distinct layers. Moving from the innermost layer outward are the metabolically active endothelium, intima (with nerves and vasa vasorum), media, and adventitia. Some vessels have fewer layers, depending on the position and function of the vessel within the circulation.

The large arteries are elastic. Their media contain concentric lamellae of perforated elastic tubes cross-linked by transverse collagen and smooth muscle. When smooth muscle contracts, the wall becomes stiffer. Smaller arteries have fewer lamellae. The media are bounded by the internal and external elastic laminae. Arterioles are less elastic, have no lamellae, and have a thin media with circular or spiral smooth muscle and inner and outer elastic laminae. Capillaries are thin walled and nonmuscular, ideal for transport of materials to and from the tissues. Veins have medial muscle but thinner walls relative to lumen diameter compared with arteries. The vascular endothelium has important metabolic characteristics, which may differ between vessel types (ie, arteries vs. veins) and different regions.[1,2]

Basic Physiology

Blood flow to a regional vascular bed is determined primarily by inflow pressure, vascular resistance, and outflow pressure. Inflow pressure is usually systemic arterial pressure. Outflow pressure approximates venous pressure but may at times exceed venous pressure if vascular tone is great enough to close the circulation above venous pressure or if external pressure impinges on the vasculature.

In a model to explain the relation of arterial pressure to flow, the circulation is represented by two capacitance vessels separated by a resistance. A standpipe full of blood is allowed to discharge its contents into the arterial vasculature (the proximal capacitance). Blood flows across the resistance site (the arterioles), traverses the venous vasculature (the distal capacitance), and drains to a reservoir at some outflow pressure (Po) (Fig. 26.1).

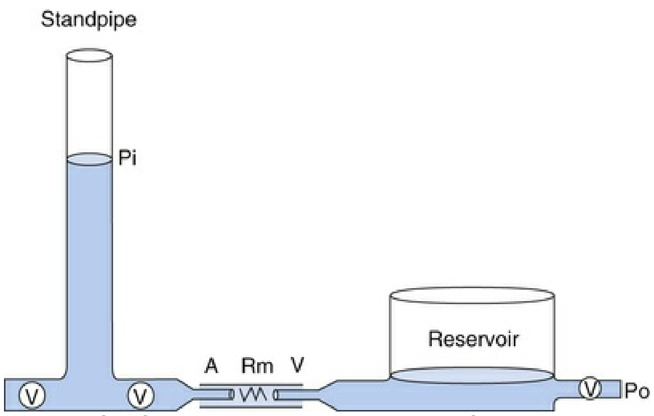

FIG. 26.1 Model for facilitating interpretation of vascular pressure-flow relations. When valves *(V)* are properly positioned, fluid filling the standpipe to height Pi discharges across the circulation to the reservoir at outflow pressure Po. *A*, artery; *Rm*, microvascular resistance; *V*, vein.

The pressure head of the system (Pi) is generated by the weight of the column of blood in the standpipe and is proportional to its height (Pi = blood column height in cm H_2O). As the standpipe discharges, the height decreases and Pi decreases. This in turn decreases the rate of flow (Q) through the vasculature. Q decreases almost linearly with Pi until the column is quite low. Ultimately, flow will cease while there is still pressure in the standpipe. The pressure at which flow ceases is the critical closing pressure of the circulation (Pc).[3] Pi below Pc is insufficient to maintain vessel patency and permit continued flow (Fig. 26.2).

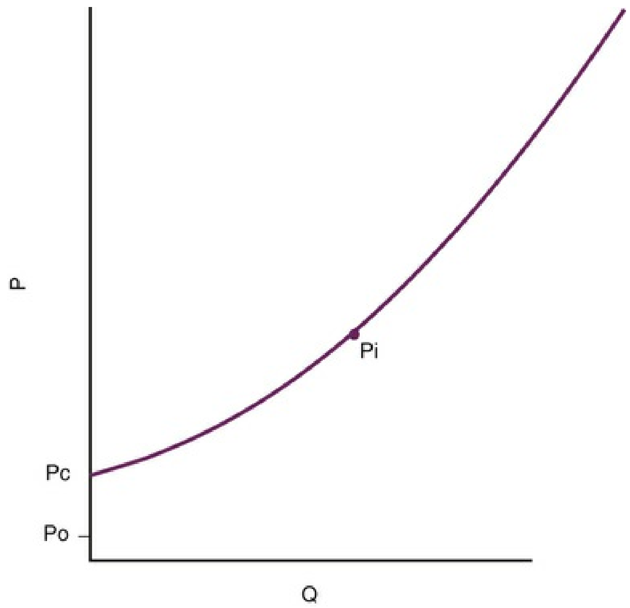

FIG. 26.2 As the standpipe in Fig. 26.1 discharges, Pi falls. Flow consequently slows and ultimately stops when Pi = Pc, the critical closing pressure of the circulation. Pi only reaches outflow pressure Po if Po ≥ Pc.

Incremental resistance to flow is generally defined as the change in pressure per unit change in flow (dPi/dQ). At pressures well above critical closing pressure, this is nearly identical to the vascular resistance (R) defined clinically as:

$$R = (Pi - Po)/Q$$

When Pi does not greatly exceed Pc but Pc does greatly exceed Po, however, incremental resistance can differ substantially from this clinical estimate. Thus an increase in Pc can be confused with a true increase in incremental resistance. For example, a diagnosis of intrinsic pulmonary vascular disease (eg, pulmonary arterial hypertension) based on measured pulmonary artery pressures in a patient receiving mechanical ventilation with high airway pressures (that raise Pc) may be spurious.

Venous Return and Cardiac Output

A second model illustrates the relationship of cardiac output to intrinsic mechanical properties of the systemic vasculature. In this model, the heart acts as a roller pump,

creating a circulation much like that achieved during venoarterial extracorporeal support (Fig. 26.3).

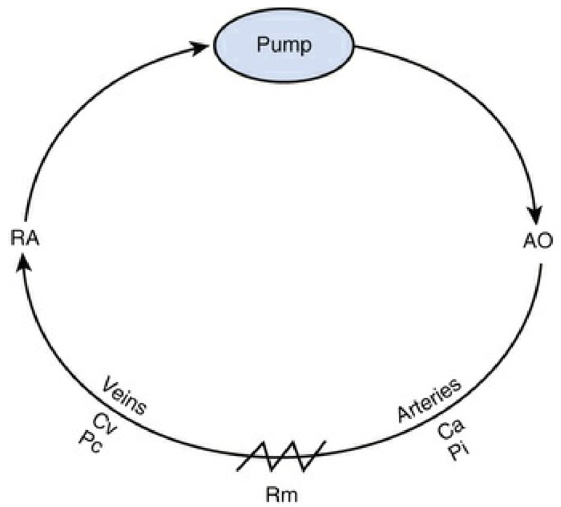

FIG. 26.3 Model for facilitating interpretation of the relation of venous return to right atrial pressure. The heart is replaced by a mechanical roller pump. The right atrium *(RA)* is drained by the pump, and blood is infused into the aorta *(AO).* Blood then traverses the arteries, which have a capacitance *(Ca)* at an inflow pressure *(Pi)* determined by flow rate and microvascular resistance *(Rm).* Blood then returns through veins having capacitance *(Cv)* and critical closing pressure *(Pc)* to the right atrium.

The roller pump displaces blood from the veins to the arteries and then across the resistance imposed by the arterioles. As Q increases, more blood resides in the arteries and less in the veins. This partitioning of blood depends on arterial capacitance (Ca), venous capacitance (Cv), and resistance to flow. At maximal Q, Pi and arterial blood volume are high and venous pressure (Pv) is low. When Pv reaches Pc, the roller pump cannot be increased further because the veins will collapse when Pv is less than Pc.

As Q is reduced, by turning down the roller pump, arterial pressure (Pi) and volume fall and Pv increases. As Q approaches zero, venous pressure approaches the mean circulatory pressure (Pm) (Fig. 26.4). The importance of this model is that it can be used to illustrate the role of venous return as an independent determinant of cardiac output.

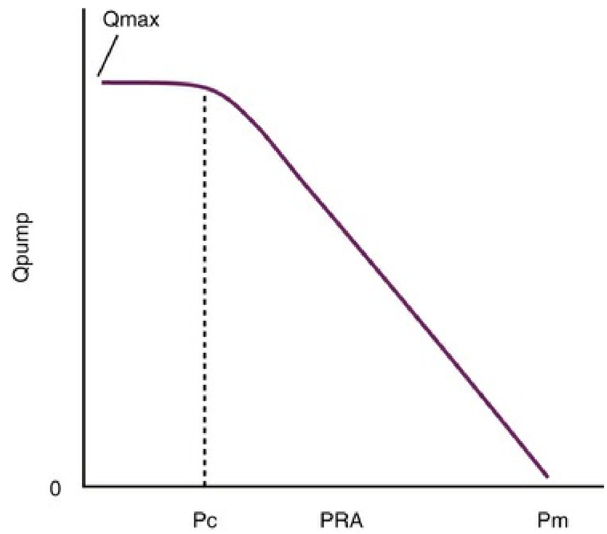

FIG. 26.4 Venous return curve. As pump flow *(Qpump)* varies, right atrial pressure *(Pra)* is altered by redistribution of blood between arteries and veins. Qpump cannot be increased above Qmax because Pra would fall below critical closing pressure *(Pc)* of the venous circulation. *Pm,* mean circulatory pressure of the vasculature at no flow.

The Starling curve that describes the relationship between preload and contractility (and hence cardiac output) is illustrated in Fig. 26.5. Over the steep portion of the curve, optimization of myocardial preload increases ventricular stroke volume. This curve (see Chapter 25) can be superimposed on the venous return curve. Cardiac output occurs at the theoretical intersection of these two curves, representing a given state of cardiac function (Starling curve) and simultaneous set of vascular characteristics (venous return curve) (see Fig. 26.5).

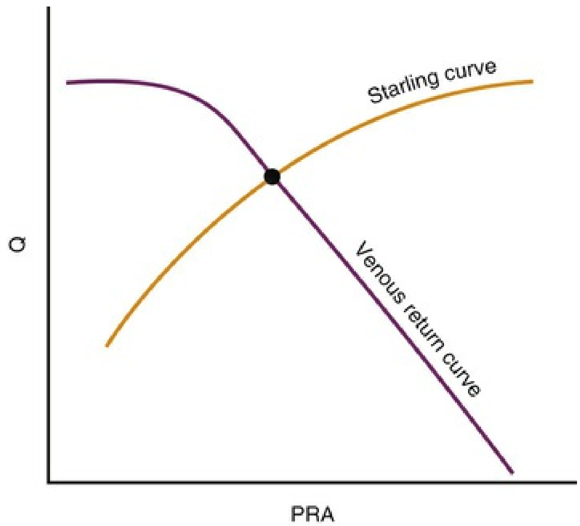

FIG. 26.5 Theoretical superimposition of venous return and Starling curves. For any state of the heart and vasculature, these curves intersect at a point that characterizes right atrial pressure *(Pra)* and cardiac output *(Q).*

It is important to recognize that the venous return curve is influenced by changes in blood volume and vascular tone. Transfusion elevates the maximal venous return

and thus cardiac output that can be achieved before the system reaches Pc. Hemorrhage has the opposite effect. Because neither transfusion nor hemorrhage directly alters vascular tone, the slope of the curve is not altered (Fig. 26.6). Both interventions alter mean circulatory pressure because they change blood volume.

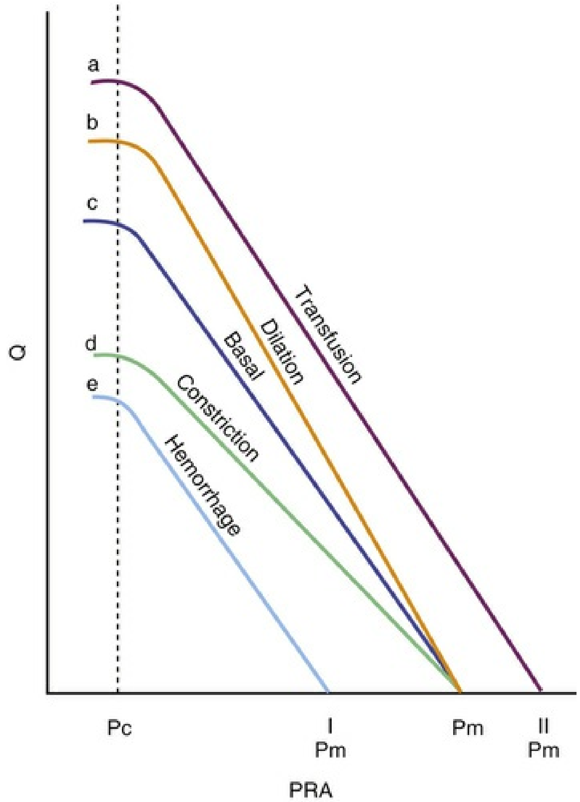

FIG. 26.6 Effects of changing blood volume and microvascular resistance on the venous return curve. Curves *a*, *c*, and *e* are parallel but have different mean circulatory pressure *(Pm)* at zero flow. Curves *b*, *c*, and *d* are nonparallel but have the same Pm. *Pc*, critical closing pressure; *Pra*, right atrial pressure.

Changes in vascular tone may alter the maximum venous return (and thus cardiac output) attainable before venous collapse (Pc), at any given intravascular volume. At zero flow, the mean pressure in the system would relate most directly to the volume of blood within the vessels. Thus changes in vascular tone change the slope of the venous return curve (see Fig. 26.6).

In clinical practice, it is unusual for any of these changes in vascular mechanics to occur in isolation. For instance, arteriolar dilation and dilation of other capacitance vessels often occur together. Arteriolar dilation and dilation of capacitance vessels have opposite effects on the venous return curve and, consequently, different effects on cardiac output. It is for this reason that vascular volume expansion is often required in combination with nitroprusside or milrinone infusions in order to ensure adequacy of cardiac output despite a reduction in afterload.

In patients with sepsis, toxic vasodilation may cause either high or low cardiac output, depending on associated changes in venous capacitance. Adequacy of vascular volume expansion, venous capacitance, vascular resistance, and the

inotropic state of the heart can all profoundly influence cardiac output in patients with sepsis. Patients in septic shock are warm only if the circulation is adequately filled, cardiac function is sufficient, and incremental resistance is low.

Critical Closing Pressure

In many organs as inflow pressure is lowered, Q decreases and ceases at a pressure —the critical closing pressure (Pc)—that is higher than venous pressure. The probable mechanism is the vascular waterfall or Starling resistor. In 1910 Jerusalem and Starling[2] described a device designed to control afterload to the left ventricle and that made possible the study of cardiac contractility.[4] The device consisted of a collapsible rubber tube traversing a pressurized glass chamber (Fig. 26.7). When pressure surrounding the rubber tube exceeded the outflow pressure set by the reservoir, surrounding pressure opposed the flow of blood and became the true outflow pressure of the device. The physiologic counterpart of this occurs in small vessels surrounded by tissue pressure. In the heart, for example, a Starling resistor effect occurs in extramyocardial coronary veins, although there is also evidence for critical closure of small arterioles. No one has yet demonstrated vessel closure directly, but this might not be necessary because as small vessels narrow when they are compressed, the wall becomes convoluted and blood cells might become obstructed by the folds even when externally the vessel does not appear to be closed.

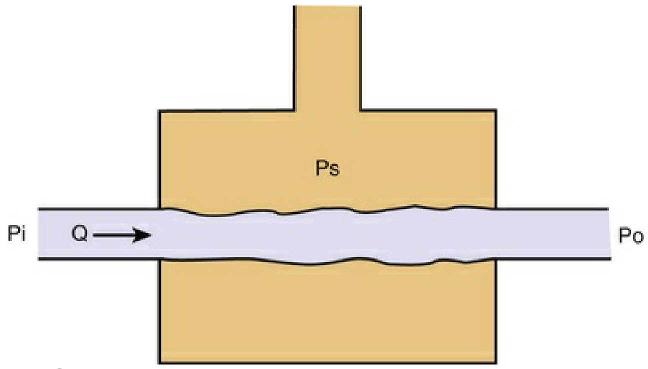

FIG. 26.7 Starling resistor is a compressible conduit exposed to surrounding pressure *(Ps)*. When Ps is less than outflow pressure *(Po)*, Ps does not oppose blood flow. When Ps is between inflow *(Pi)* and outflow pressures, it opposes blood flow. No flow is possible when Ps exceeds Pi.

Autoregulation

In all organs, when inflow pressure is suddenly raised or lowered while oxygen consumption remains constant, flow rises or falls transiently but then returns to its former value; the phenomenon is termed *autoregulation*. Several mechanisms, particularly related to oxygen sensing, have been implicated in this response, but the precise mechanisms are likely complex and multifactorial. For example, studies have described a role for nitric oxide (NO) carried to the tissues by hemoglobin in the form of S-nitrosohemoglobin.[5-7] Other locally produced gases such as hydrogen sulfide[8] and carbon monoxide[9,10] may also play a role. Importantly, some

autoregulatory mechanisms are specific to individual microcirculations (eg, macula densa signaling in the renal circulation).

Distensibility and Compliance

The distensibility of a vessel is defined as the change in volume as a proportion of the initial volume for a given change in pressure:

$$\text{Distensibility} = \frac{\Delta V}{\Delta P} \times \frac{1}{V},$$

where *V* is volume and *P* is pressure. Veins are much thinner than arteries and are about eight times more distensible. Multiplying distensibility by volume yields DV/DP, which is the definition of compliance. Because venous volume is usually more than three times arterial volume, venous compliance is about 20- to 30-fold greater than arterial compliance. As a result, whenever fluids are infused, the veins accommodate the bulk of the fluid volume.

Vascular Resistance

Under normal circumstances, vascular resistance is the major control of organ flow and can be understood by considering the resistance of a Newtonian liquid passing through a rigid tube as defined by the Hagen-Poiseuille equation:

$$R = \left(\frac{8}{\pi}\right)\left(\frac{l}{r^4}\right)\eta$$

where *R* is resistance, *l* is tube length, *r* is the internal radius of the tube, and η is the fluid viscosity. Blood is not a Newtonian fluid, but this fact does not affect the accuracy of calculated vascular resistance much. However, vascular beds do contain many “tubes” in parallel. Thus for vascular systems, a factor k is added that represents the number of vessels. The equation thus becomes:

$$R = \left(\frac{8}{\pi}\right)\left(\frac{l}{kr^4}\right)\eta$$

Because the length and number of vessels and blood viscosity are relatively constant at any one time, change in vessel radius is the major factor responsible for a dynamic change in vascular resistance; because of the fourth power factor, small changes in radius cause large changes in resistance. Vessel radius is influenced by vascular elasticity and transmural pressure but is mainly regulated by changes in vessel wall smooth muscle tone.

Vascular Impedance

Resistance is strictly a steady state concept. In a pulsatile system the factors affecting the relationship of pressure dissipation to flow are resistance due to friction and

viscosity, fluid inertia, and vessel wall compliance, which combine to produce an *impedance* to flow that varies with frequency. At zero frequency, steady state resistance is approximated by the change in mean pressure over flow, but there are substantial contributions made by the first three harmonics that are ignored by this calculation.

Local Regulatory Mechanisms

Regions of the circulation may differ markedly in their patterns of vascular regulation. A regulatory stimulus can have multiple effects that differ from one location to another. An agent that potently regulates vascular resistance in one region of the circulation may have no effect in another. For example, during hemorrhagic shock, flow is maintained to heart and brain but reduced to muscle, kidneys, and gut.

Vascular tone is strongly influenced by several mechanisms: (1) innervation and neural processes, (2) circulating endocrine and neuroendocrine mediators, (3) local metabolic products, (4) blood gas composition, (5) endothelial-derived factors, and (6) myogenic processes.

Innervation and Neural Processes

Receptors responsive to neural products (eg, norepinephrine and acetylcholine) are found throughout the circulation. Nevertheless, innervation and receptor distribution are organ specific, allowing rapid, patterned, coordinated redistribution of blood flow and an orchestrated response to events, such as hypoxia, changes in posture, and hemorrhage. Although these receptors respond to circulating agonists (including adrenal epinephrine), as well as to those liberated locally, they are generally associated with innervation by autonomic nerves. In general, presynaptic α-adrenergic stimulation causes norepinephrine reuptake, whereas postsynaptic α-adrenergic stimulation causes norepinephrine release and vasoconstriction. β-Adrenergic stimulation generally causes vasodilation. Cholinergic stimulation (whether sympathetic or parasympathetic) generally causes vasodilation (see Chapters 33 and 125).

Circulating Endocrine and Neuroendocrine Mediators

Humoral regulators of vascular tone include angiotensin, arginine vasopressin, bradykinin, histamine, and serotonin. Of less certain significance are aldosterone, thyroxine, antinatriuretic peptide, and various reproductive hormones. Most of these have both direct effects and secondary effects, which tend to be organ specific or regional in nature. Angiotensin plays a special role in the homeostasis of blood pressure and is produced in hemorrhagic or hypovolemic shock. It causes generalized vasoconstriction in both systemic and pulmonary circulations, but locally it stimulates the release of vasodilating prostaglandins in lung and kidney. Bradykinin is a potent pulmonary and systemic vasodilator released locally by the action of proteolytic enzymes on kallikrein after tissue injury. Histamine is released by mast cells in response to injury and is also a potent vasodilator in most regions of the circulation, but it causes vasoconstriction in the lung.

Local Metabolic Products

Local metabolic regulation of vasomotor tone provides an ideal homeostatic mechanism whereby metabolic demand can directly influence perfusion. The precise mechanisms underlying the coupling of blood flow with metabolic activity remain unclear. One theory holds that as the metabolic rate increases, so too does the formation of some vasodilating substance. Thus the regional vasculature relaxes, allowing more oxygen to be delivered in support of this work. As flow rises, the metabolites are washed out, restoring their concentration to normal. Adenosine, for instance, which accumulates locally when tissue metabolism is high and tissue oxygenation is marginal, causes pronounced vasodilation in the coronary, striated muscle, splanchnic, and cerebral circulations. Another example is potassium, which is released from muscle in response to increased work, ischemia, and hypoxia. Hypokalemia causes vasoconstriction, and hyperkalemia, within the physiologic range, causes vasodilation.

An increasing amount of data demonstrates the importance of the local redox state on the regulation of blood flow through the microcirculation. Reactive oxygen species, such as superoxide, hydrogen peroxide, and peroxynitrite, have been shown to influence normal regulatory processes and participate in the pathophysiology of a wide array of cardiovascular disorders. For example, the rapid reaction of NO with the superoxide anion results in the formation of peroxynitrite, a potent oxidant. Although peroxynitrite is known to have cytotoxic properties, under normal conditions peroxynitrite inhibits leukocyte adherence and platelet aggregation without evidence of cellular injury.[11] In disease states, however, peroxynitrite can lead to protein nitration and DNA damage. In addition, elevated levels of superoxide may decrease the bioavailability of NO leading to abnormal vasomotion.[12]

Blood Gas Composition

Tissue levels of oxygen and carbon dioxide have been shown to reflect adequacy of perfusion and oxygen delivery.[13] These blood gases are potent determinants of regional blood flow and have effects that differ from one region of the circulation to another. They also have a more general effect mediated by carotid chemoreceptors.

Endothelial-Derived Factors

The vascular endothelial cells are capable of producing a variety of vasoactive substances, which participate in the regulation of normal vascular tone. These substances, such as NO, CO, H_2S, and endothelin-1 (ET-1), are capable of producing vascular relaxation and/or constriction, modulating the propensity of the blood to clot, and inducing and/or inhibiting smooth muscle migration and replication[14] (Fig. 26.8). Understanding the role of the vascular endothelium and the factors it produces in regulating blood flow in health and disease has resulted in several treatment strategies that target, mimic, or augment endothelial processes. Therapies that have been used with variable success include inhaled NO for pulmonary hypertension; L-arginine supplementation for coronary artery disease and the pulmonary vasculopathy of sickle cell disease; phosphodiesterase inhibitors (ie, sildenafil, which prevents the breakdown of cGMP) for pulmonary hypertensive disorders; endothelin receptor antagonists for pulmonary hypertensive disorders and vasospasm following subarachnoid hemorrhage; and NO inhibitors for refractory

hypotension secondary to sepsis.[15-20] Indeed, many older therapies used to promote vascular relaxation, such as nitrovasodilators, affect endothelial function, a fact not appreciated until relatively recently.

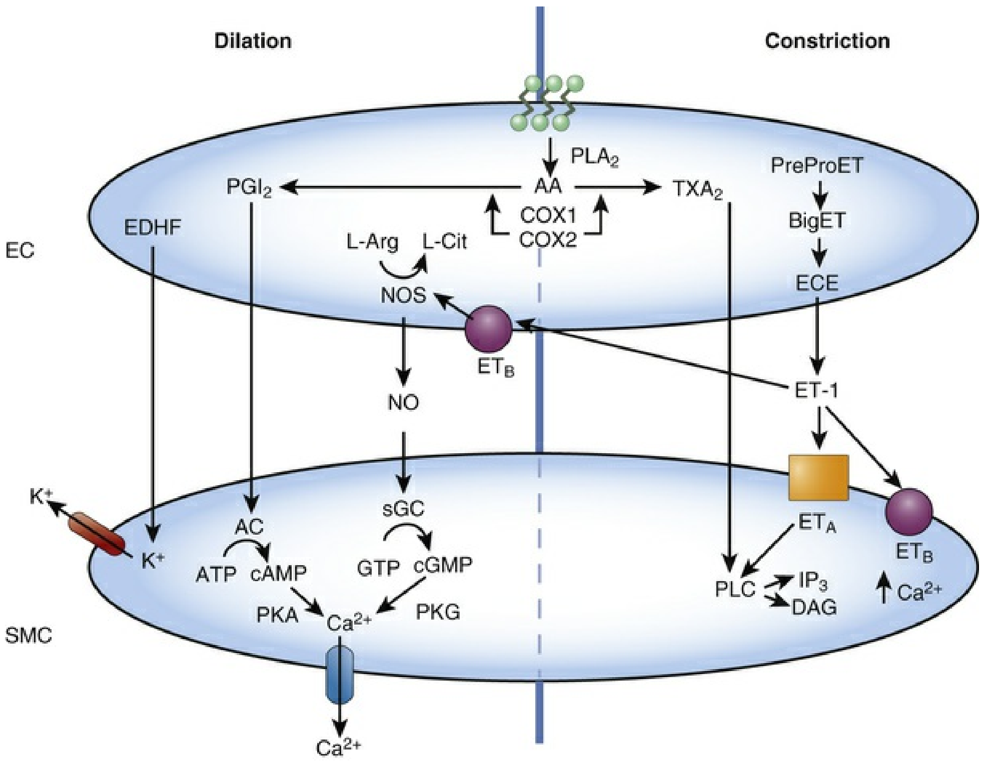

FIG. 26.8 Schematic of some endogenous vasoactive agents produced by the vascular endothelium. *AA,* arachidonic acid; *AC,* adenylate cyclase; *ATP,* adenosine triphosphate; *cAMP,* cyclic adenosine monophosphate; *cGMP,* cyclic guanosine monophosphate; *COX,* cyclooxygenase; *DAG,* diacylglycerol; *EC,* endothelial cell; *ECE,* endothelin-converting enzyme; *EDHF,* endothelial-derived hyperpolarizing factor; *ET-1,* endothelin-1; *GTP,* guanosine triphosphate; *IP3,* inositol 1,4,5, triphosphate; *L-arg,* L-arginine; *L-cit,* L-citrulline; *NO,* nitric oxide; *NOS,* nitric oxide synthase; *PGI2,* prostacyclin; *PKA,* protein kinase A; *PKC,* protein kinase C; *PLA,* phospholipase A2; *sGC,* soluble guanylate cyclase; *SMC,* smooth muscle cell; *TXA2,* thromboxane A2.

NO is a labile humoral factor produced by NO synthase from L-arginine in the vascular endothelial cell. NO diffuses into the smooth muscle cell and produces vascular relaxation by increasing concentrations of guanosine 3′5′-monophosphate (cGMP), via the activation of soluble guanylate cyclase. NO is released in response to a variety of factors including shear stress (flow) and the binding of certain endothelium-dependent vasodilators (such as acetylcholine, ATP, and bradykinin) to receptors on the endothelial cell. Basal NO release is an important mediator of both resting pulmonary and systemic vascular tone in the fetus, newborn, and adult, as well as a mediator of the fall in pulmonary vascular resistance normally occurring at the time of birth.[21] Dynamic changes in NO release are fundamental to the regulation of all vascular beds.

CO is a labile humoral factor produced by the action of hemoxygenase on heme in

many tissues, including endothelial cells. Hemoxygenase-1 is constitutive and hemoxygenase-2 is inducible. CO interacts with NO, is an independent stimulator of cGMP, relaxes smooth muscle, inhibits its replication, and has powerful antithrombotic and antiinflammatory effects. It is beginning to enter the field of clinical medicine.[10,22]

Hydrogen sulfide (H2S) is produced in most tissues by a variety of mechanisms and may be the ultimate sensor that is stimulated by oxygen deficit or excess.[8]

ET-1 is a 21 amino acid polypeptide also produced by vascular endothelial cells.[23] The vasoactive properties of ET-1 are complex, and studies have shown varying hemodynamic effects on different vascular beds. However, its most striking property is its sustained hypertensive action. In fact, ET-1 is the most potent vasoconstricting agent discovered, with a potency 10 times that of angiotensin II. The hemodynamic effects of ET-1 are mediated by at least two distinctive receptor populations, ETA and ETB. The ETA receptors are located on vascular smooth muscle cells and mediate vasoconstriction, whereas the ETB receptors may be located on endothelial cells and mediate both vasodilation and vasoconstriction. Individual endothelins occur in low levels in the plasma, generally below their vasoactive thresholds. This suggests that they are primarily effective at the local site of release. Even at these levels, they may potentiate the effects of other vasoconstrictors such as norepinephrine and serotonin.[24] The role of endogenous ET-1 in the regulation of normal vascular tone is presently unclear. Nevertheless, alterations in endothelin-1 have been implicated in the pathophysiology of a number of disease states.[25]

Endothelial-derived hyperpolarizing factor (EDHF), a diffusible substance that causes vascular relaxation by hyperpolarizing the smooth muscle cell, is another important endothelial factor. EDHF has not yet been identified, but current evidence suggests that the action of EDHF is dependent on K+ channels (Fig. 26.8). Activation of potassium channels in the vascular smooth muscle results in cell membrane hyperpolarization, closure of voltage-dependent calcium channels, and ultimately vasodilation. Potassium channels are also present in endothelial cells. Activation within the endothelium results in changes in calcium flux and may be important in the release of NO, prostacyclin, and EDHF. Potassium channel subtypes include ATP-sensitive K+ channels, Ca2+-dependent K+ channels, voltage-dependent K+ channels, and inward-rectifier K+ channels.

The breakdown of phospholipids within vascular endothelial cells results in the production of the important byproducts of arachidonic acid, including prostacyclin (PGI2) and thromboxane (TXA2). PGI2 activates adenylate cyclase, resulting in increased cAMP production and subsequent vasodilation, whereas TXA2 results in vasoconstriction via phospholipase C signaling (see Fig. 26.8). Other prostaglandins and leukotrienes also have potent vasoactive properties.

Myogenic Processes

In 1902 Bayliss described an intrinsic increase in vascular tone in response to elevated intravascular pressure.[26] This myogenic response results in alterations in vascular tone following changes in transmural pressure or stretch. This response is especially important at the arteriolar level and is thought to participate in regional autoregulation. Increases in intravascular pressure and/or stretch result in an increase in arteriolar smooth muscle tone, while decreasing pressures have the reverse effect. The precise mechanisms mediating this response are unclear, but a

role for dynamic changes in intracellular Ca^{2+} and myosin light chain phosphorylation has been documented.[27] More recent work has focused on the role of tyrosine phosphorylation pathways, ENaC, transient receptor potential (TRP) channels, potassium channels, and alterations in Ca^{2+} sensitivity in this response.[28-32] Moreover, the myogenic response varies between the regional circulations and between vessels within a given circulation.

Regional Circulations

Pulmonary Circulation

Maldevelopment and/or maladaptation of the pulmonary vascular bed are important components of several neonatal and infant disease states (ie, chronic lung disease, persistent pulmonary hypertension of the newborn, and congenital heart disease). In addition, strategies aimed at altering postnatal pulmonary vascular resistance are commonly used in the management of these patients. Therefore an understanding of the regulation of postnatal pulmonary vascular tone is important.

The morphologic development of the pulmonary circulation affects the physiologic changes that occur in the perinatal period. In the fetus and neonate, small pulmonary arteries have thicker muscular coats than similarly located arteries in the adult. This muscularity is, in large part, responsible for the pulmonary vascular reactivity and high resistance found in the fetus. Within the first several weeks after birth, the medial smooth muscle involutes and the thickness of the media of the small pulmonary arteries decreases rapidly and progressively.[33]

Following this perinatal transition, the medial layers of the proximal pulmonary vascular bed are completely encircled by smooth muscle. Moving distally, muscularization becomes incomplete (arranged in a spiral or helix) and disappears completely from the most peripheral arterioles.[34] In these arterioles, an incomplete pericyte layer is found within the endothelial basement membrane. Smooth muscle precursor cells reside in the nonmuscular portions of the partially muscular pulmonary arteries. Under certain conditions, such as hypoxia, these cells may rapidly differentiate into mature smooth muscle cells.

Subsequently, from infancy to adolescence, the arteries undergo progressive peripheral muscularization. In the adult, complete circumferential muscularization extends peripherally such that the majority of small pulmonary arteries are completely muscularized.

Normal Fetal Circulation

In the fetus, normal gas exchange occurs in the placenta and pulmonary blood flow is low, supplying only nutritional requirements for lung growth and performing some metabolic functions. Pulmonary blood flow in near-term lambs is between 8% and 10% of total output of the heart.[35] Pulmonary blood flow is low despite the dominance of the right ventricle, which in the fetus ejects about two-thirds of total cardiac output. Most of the right ventricular output is diverted away from the lungs through the widely patent ductus arteriosus to the descending thoracic aorta, from which a large proportion reaches the placenta through the umbilical circulation for oxygenation. Fetal pulmonary arterial pressure increases with advancing gestation. At term, mean pulmonary arterial pressure is about 50 mm Hg, generally exceeding

mean descending aortic pressure by 1 to 2 mm Hg.[36] Pulmonary vascular resistance early in gestation is extremely high relative to that in the infant and adult, probably due to the low number of small arteries. Pulmonary vascular resistance falls progressively during the last half of gestation, new arteries develop, and cross-sectional area increases; however, baseline pulmonary vascular resistance is still much higher than after birth.[36,37]

Changes in the Pulmonary Circulation at Birth

After birth, with initiation of ventilation by the lungs and the subsequent increase in pulmonary and systemic arterial blood O_2 tensions, pulmonary vascular resistance decreases and pulmonary blood flow increases by 8- to 10-fold to match systemic blood flow. This large increase in pulmonary blood flow increases pulmonary venous return to the left atrium, increasing left atrial pressure. Then the valve of the foramen ovale closes, preventing any significant atrial right-to-left shunting of blood. In addition, the ductus arteriosus constricts and closes functionally within several hours after birth, effectively separating the pulmonary and systemic circulations. Mean pulmonary arterial pressure decreases and, by 24 hours of age, is approximately 50% of mean systemic arterial pressure. Adult values are reached 2 to 6 weeks after birth[38,39] (Fig. 26.9).

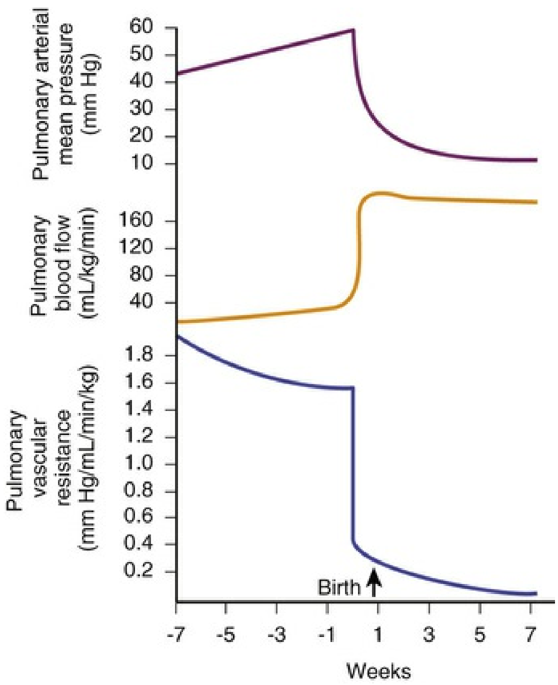

FIG. 26.9 Changes in mean pulmonary arterial pressure, pulmonary blood flow, and pulmonary vascular resistance at birth. (Data from Morin FC III, Egan E. Pulmonary hemodynamics in fetal lambs during development at normal and increased oxygen tension. J Appl Physiol. 1993;73:213-218; Soifer SJ, Morin FC III, Kaslow DC, et al. The developmental effects of prostaglandin D2 on the pulmonary and systemic circulations in the newborn lamb. J Dev Physiol. 1983;5:237-250.)

The decrease in pulmonary vascular resistance with ventilation and oxygenation at birth is regulated by a complex and incompletely understood interplay between

metabolic and mechanical factors, which in turn are triggered by the ventilatory and circulatory changes that occur at birth. Physical expansion of the fetal lamb lung without changing O_2 tension increases fetal pulmonary blood flow and decreases pulmonary vascular resistance, but not to newborn values.[40] Mechanical factors include the replacement of fluid in the alveoli with gas, which allows unkinking of the small pulmonary arteries, and radial traction on extra-alveolar vessels that maintain their patency.[41] Physical expansion of the lung also releases vasoactive substances such as PGI2.

Ventilation of the fetus without oxygenation produces partial pulmonary vasodilatation, while ventilation with air or oxygen produces complete pulmonary vasodilatation. The exact mechanisms of oxygen-induced pulmonary vasodilation during the transitional circulation remain unclear. The increase in alveolar or arterial O_2 tension may decrease pulmonary vascular resistance by either directly dilating the small pulmonary arteries or indirectly stimulating the production of vasodilator substances such as PGI2 or NO.

Therefore there are at least two components to the decrease in pulmonary vascular resistance with the initiation of ventilation and oxygenation. Both components are necessary for the successful transition to extrauterine life. Control of the perinatal pulmonary circulation reflects a balance between factors producing pulmonary vasoconstriction (low O_2, leukotrienes, and other vasoconstricting substances) and those producing pulmonary vasodilatation (high O_2, PGI2, NO, and other vasodilating substances). The dramatic increase in pulmonary blood flow with the initiation of ventilation and oxygenation at birth reflects a shift from active pulmonary vasoconstriction in the fetus to active pulmonary vasodilatation in the newborn.

Failure of the pulmonary circulation to undergo this normal fall in pulmonary vascular resistance at birth (persistent pulmonary hypertension of the newborn) is associated with a variety of conditions including aspiration syndromes, sepsis, in-utero stress events, and certain congenital heart defects (eg, obstruction of pulmonary venous drainage, single ventricle with restrictive atrial septum).

Regulation of Postnatal Pulmonary Vascular Resistance

After the immediate postnatal state, the pulmonary circulation is maintained in a dilated, low-resistance state. Because the inflow pressure of the pulmonary circulation is quite low, there is a vertical gradation to the distribution of blood flow in the lung. Hydrostatic pressure must be adjusted for vertical height above the left atrium, both at the inflow and outflow of every alveolar capillary unit. For example, given a pulmonary artery mean pressure of 20 cm H_2O (zeroed at the level of the left atrium), an alveolar-capillary unit 12 cm above the left atrium will face an inflow pressure of only 8 cm H_2O. A left atrial pressure of 5 cm H_2O would generate no opposing outflow pressure to alveolar capillary units more than 5 cm above the left atrium. Critical closing pressure of postcapillary vessels would therefore set outflow pressure for a unit 10 cm above the left atrium. Were intrinsic vascular resistance identical throughout the lung, flow at any vertical height would be determined by hydrostatic driving pressure (inflow-outflow) and would be greatest at the base and least at the apex of the lung. West, Dollery, and Naimark reported that this phenomenon partitions the lung into three vertical regions (Fig. 26.10).[42] Zone I

vessels are higher above the left atrium than pulmonary artery pressure (expressed in cm H_2O) and are not perfused by the pulmonary artery. Zone II vessels lie above the height defined by the hydrostatic left atrial pressure but below the height of pulmonary artery pressure. These units are perfused in proportion to the driving pressure across them, which is approximately pulmonary artery pressure less vertical height (or critical closing pressure, whichever is higher). Zone III vessels lie at a vertical height less than outflow pressure expressed in cm H_2O. Driving pressure across these units is independent of height because inflow and outflow pressures are comparably influenced by gravity. Of note, in a supine neonate, there is likely no Zone I.

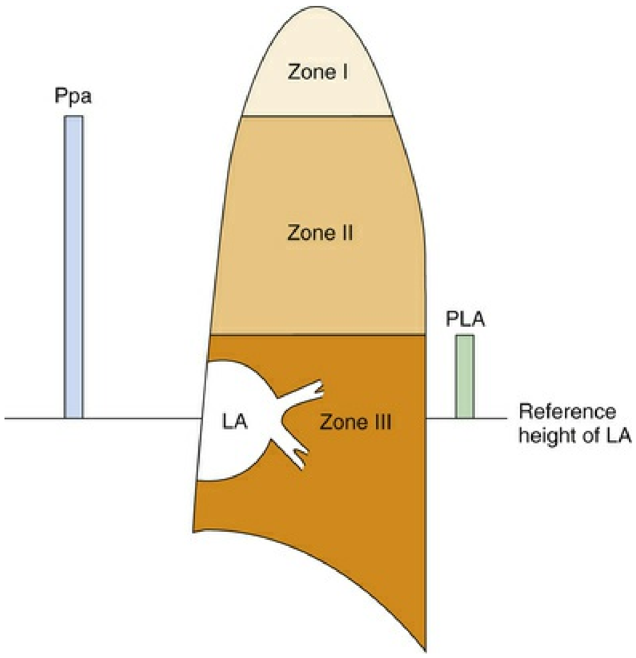

FIG. 26.10 The lung is divided vertically into three regions. Zone I alveolar capillary units are unperfused because they see no functional inflow pressure. Zone II units are perfused in proportion to their height above the left atrium *(LA)*. Zone III vasculature is more uniformly perfused because gravity has comparable effects on inflow and outflow pressures. (Redrawn from Fuhrman BP. Regional circulation. In: Fuhrman BP, Shoemaker WC, eds. Critical Care: State of the Art, vol 10. Fullerton, CA: Society of Critical Care Medicine; 1989.)

Small pulmonary arteries course along with the branching airways, and small pulmonary vessels are intimately related with alveoli. Therefore airway pressure can directly modulate pulmonary blood flow.[43] Alveolar pressure can be loosely translated into surrounding pressure for alveolar vessels. Positive airway pressure applied to the lung can impinge on alveolar vessels whenever alveolar pressure exceeds the other determinants of outflow pressure. During positive pressure ventilation, outflow pressure of the pulmonary circulation may be determined predominantly by the mechanics of ventilation. The lung is partitioned into zones, but the distribution of flow becomes a complex function of alveolar pressure, as well as left atrial and critical closing pressures.

To further complicate this view of the pulmonary circulation, lung volume and

alveolar pressure both change during positive pressure ventilation. During inspiration, extra-alveolar vessels are dilated by radial traction, reducing their resistance to flow, whereas alveolar vessels narrow and elongate.[44] During lung inflation, alveolar surface tension rises, diminishing the transmission of alveolar pressure to alveolar vessels. There is also evidence that, in the infant lamb, lung stretch may directly augment pulmonary vascular tone in a manner that is dependent on calcium flux and subject to calcium channel blockade using verapamil. In fact, it is clear that mechanical ventilation can have profound direct effects on the intact pulmonary circulation that depends on the waveform of airway pressure applied, not on mean airway pressure alone.

In heterogeneous lung disease, the application of positive airway pressure can modulate and redistribute blood flow away from ventilated and toward unventilated regions of the lung by directly increasing the pulmonary vascular resistance of lung segments exposed to elevated airway pressure, that is, segments not protected by consolidation or airway obstruction.[44]

Two of the most important factors affecting pulmonary vascular resistance in the postnatal period are oxygen concentration and pH. Decreasing oxygen tension or pH elicit pulmonary vasoconstriction of the resting pulmonary circulation.[45] Alveolar hypoxia constricts pulmonary arterioles, diverting blood flow away from hypoxic lung segments and toward well-oxygenated segments.[46] This enhances ventilation-perfusion matching. This is a unique pulmonary vascular response to hypoxia, which is probably greater in the younger animal than the adult. The mechanism of alveolar hypoxic pulmonary vasoconstriction remains to be defined and is the subject of several extensive reviews. Acidosis potentiates hypoxic pulmonary vasoconstriction, and alkalosis reduces it.[45] The exact mechanism of pH-mediated pulmonary vasoactive responses also remains incompletely understood but appears to be independent of $PaCO_2$. Alveolar hyperoxia and alkalosis are often used to relax pulmonary vascular tone because they generally relieve pulmonary vasoconstriction while having little apparent effect on the systemic circulation as a whole. However, detrimental effects of hypocarbia or respiratory alkalosis on cerebral and myocardial blood flow may occur.

The lung is innervated, but neural effects on pulmonary vascular resistance appear to be of little consequence on basal tone. However, pulmonary neurohumoral receptors are sensitive to α-adrenergic, β-adrenergic, and dopaminergic agonists. Therefore vasoactive agents that stimulate these receptors will affect the vascular tone of both the pulmonary and systemic circulations. The degree of pulmonary to systemic alterations induced by these agents is variable and often dictated by the relative tone of each vascular bed. Therefore the response of these agents is difficult to predict in an individual critically ill patient.

A selective pulmonary vasodilator was long sought for treatment of pulmonary hypertension because, with the exception of oxygen, the response of the pulmonary circulation to humoral vasoactive agents is generally similar to that of the systemic circulation. To date, inhaled NO is the most commonly used agent for selective pulmonary vascular dilation. It is noteworthy that its selectivity is not based on a differential effect in the pulmonary and systemic circulations. Rather, when delivered as an inhaled gas, NO is rapidly bound to hemoglobin and inactivated, thus limiting its effects to the pulmonary circulation. Inhaled prostacyclin is another agent that offers relative pulmonary vascular selectivity due to its rapid

metabolism.[47]

Cerebral Circulation

The brain makes up 2% of body mass, receiving approximately 14% of the cardiac output while accounting for close to 20% of the body's O_2 consumption in adults, up to 30% of cardiac output, 50% or more of total oxygen usage, and up to 98% usage of produced hepatic glucose in neonates. Other organ systems receive a larger percentage of the total cardiac output (eg, the lung) and use greater amounts of oxygen (eg, skeletal muscle), but the brain is unique in its intolerance for diminished blood flow. In fact, although some favorable outcomes have been reported, severe, if not irreversible, damage occurs often after just minutes of circulatory arrest under normal conditions.[48]

The cranium has three compartments: tissue, cerebral spinal fluid (CSF), and blood. The Monro-Kellie doctrine states that these compartments occupy a relatively fixed space and that an increase in one compartment can only occur at the expense of another. For example, with brain swelling, CSF and cerebral venous blood must be displaced if intracranial pressure (ICP) is to remain unchanged. As the limits of CSF and blood evacuation are approached, ICP rises. Raised ICP and/or venous obstruction can impede cerebral blood flow (CBF). Cerebral perfusion pressure (CPP), defined as the difference between the mean arterial pressure and the ICP, is thus a more accurate descriptor of cerebral inflow pressure. CBF will decline when the CPP falls below the lower limit of the autoregulatory curve. In the setting of raised ICP this will occur even in the face of elevated systemic arterial pressures.

At rest, cerebral oxygen consumption is surprisingly high. Glucose is the primary energy substrate, although ketones can be used during periods of starvation. The brain has no functional capacity to store energy and thus is completely dependent on a steady supply of O_2 as up to 92% of its ATP production results from the oxidative metabolism of glucose.[48]

An important feature unique to the cerebral circulation is the presence of a blood-brain barrier (BBB). The vascular endothelium of brain capillaries forms a continuous sheet, with adjacent cells joined by tight junctions. Unlike the endothelium of non-neural capillaries, there are no intercellular clefts through which water-soluble particles can traverse and there is markedly diminished pinocytosis. Lipid-soluble substances, CO_2, and O_2, however, can freely diffuse across the endothelium. Metabolically important components, such as glucose, lactate, and amino acids, depend on specific carrier proteins to facilitate their diffusion into the brain. Furthermore, the BBB has a biochemical component, with high levels of degradative enzymes that protect the vascular smooth muscle and extracellular fluid from the effects of circulating vasoactive substances, such as catecholamines. Thus as a result of the BBB, the cerebral vasculature responds differently from other vascular beds to humoral stimuli. However, humoral stimuli can significantly alter the vascular tone of large cerebral arteries and can affect blood flow to parts of the brain that lack a complete BBB, such as the choroid plexus, median eminence, and area postrema.[49]

It has been recognized for nearly 80 years that CBF remains constant over a wide range of mean systemic arterial pressures (Fig. 26.11).[50] Constant CBF is maintained in the face of increasing inflow pressures by compensatory vasoconstriction.

Conversely, in the setting of low systemic arterial pressures (ie, low inflow pressures) the cerebral vasculature dilates in order to maintain steady CBF. At systemic arterial pressures outside the autoregulatory range, further dilation or constriction can no longer maintain blood flow. At high pressures, disruption of the BBB ensues with subsequent edema and even hemorrhage from ruptured cerebral vessels. At low pressures, CBF begins to fall with continued decreases leading to ischemia and ultimately brain death.[51] Importantly, normal cerebral autoregulation can be impaired in the setting of disease. Traumatic brain injury, subarachnoid hemorrhage, and stroke, for example, can all abolish or impair the normal autoregulatory response.[52,53]

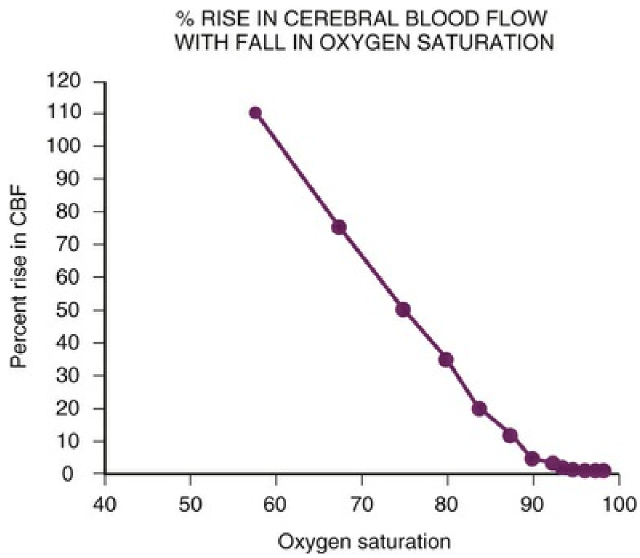

FIG. 26.12 Arterial hypoxia dilates cerebral vessels and maintains cerebral oxygen delivery. *CBF*, cerebral blood flow. (Redrawn from Fuhrman BP. Regional circulation. In: Fuhrman BP, Shoemaker WC, eds. Critical Care: State of the Art, vol 10. Fullerton, CA: Society of Critical Care Medicine; 1989.)

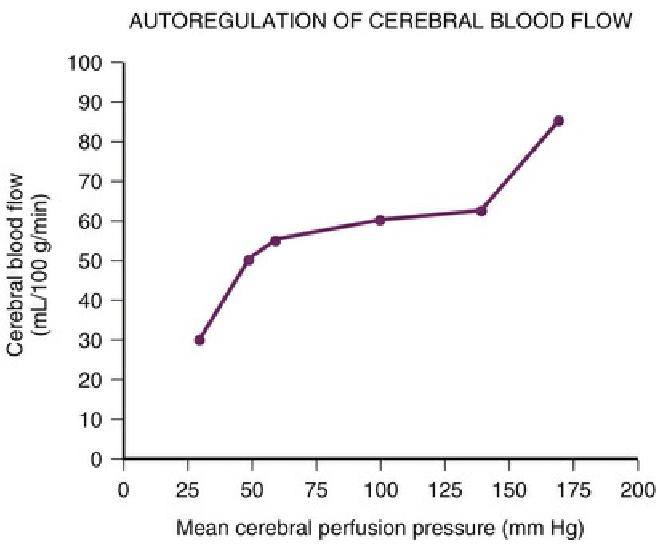

FIG. 26.11 Cerebral blood flow (CBF) autoregulates at perfusion

pressures between 50 and 160 mm Hg. Below 50 mm Hg, CBF falls. Above 160 mm Hg, CBF rises. (Redrawn from Fuhrman BP. Regional circulation. In: Fuhrman BP, Shoemaker WC, eds. Critical Care: State of the Art, vol 10. Fullerton, CA: Society of Critical Care Medicine; 1989.)

The brain's ability to autoregulate flow is well established, but the mechanisms underlying it are not completely understood. A myogenic response appears to be especially important in the setting of raised CPP. Large- and medium-sized cerebral arteries, including the ICA, have been shown to constrict both in vitro and in vivo in response to elevated transmural pressures. Although small arteries and arterioles primarily modulate cerebral resistance during normotension, at higher pressures the large cranial vessels dominate. Thus at high perfusion pressures, smaller, more delicate vessels are protected by changes in upstream resistance.

In marked contrast to other vascular beds, neural stimuli have relatively little effect on basal CBF. Cerebral vessels display extensive perivascular innervation, especially by the sympathetic nerves arising from the superior cervical sympathetic ganglia, but the brain is well protected from circulating catecholamines by the BBB. Thus many of the vasoactive agents used in the critical care setting (α- and β-adrenergic agonists) have minimal effects of resting cerebral vascular tone. Mild to moderate electrical stimulation, as well as surgical resection of both the sympathetic and parasympathetic nervous systems, does not alter cerebral vascular tone under resting conditions. However, vigorous sympathetic stimulation, as would occur with strenuous exercise or hypertension, does result in vasoconstriction of large- and medium-sized cerebral vessels. Thus while a neurogenic mechanism may not mediate cerebral vascular resistance under normal conditions, it does provide protection during times of stress.[54] Indeed, patients with chronic hypertension have been shown to have a rightward shift of the autoregulatory curve.

As in other vascular beds, it appears that CBF is coupled to changes in metabolism.[55] For example, hypothermia decreases the cerebral metabolic rate of oxygen ($CMRO_2$), and therefore CBF, in both animal and human studies.[56-58] Seizure activity and fever both increase the $CMRO_2$ and CBF, which explains the deleterious consequences of both conditions for patients with raised ICP.[59] The mechanisms underlying this coupling of blood flow and metabolism are still unclear. A number of substances have been shown to affect cerebrovascular tone. These include carbon dioxide, oxygen, hydrogen ions, lactic acid, histamine, potassium ions, prostaglandin, ET-1, NO, and adenosine.

Carbon dioxide plays a critical role in the regulation of CBF. In fact, a linear increase in CBF is seen with increasing $PaCO_2$, making CO_2 one of the most potent known cerebral vasodilators.[60] Carbon dioxide exerts its effect via a reduction of the perivascular pH. Whereas arterial H+ cannot cross the BBB, CO_2 can easily diffuse into the brain. Carbonic anhydrase facilitates the reaction between CO_2 and H_2O forming carbonic acid with subsequent dissociation producing H+ ions. Perivascular acidosis dilates the cerebral vasculature, while alkalosis leads to vasoconstriction.[61] In this way the cerebral vasculature is distinct in that respiratory acidosis and alkalosis will alter tone and CBF, while metabolic acidosis and alkalosis will not.[60,62] Interestingly, abnormal CO_2 reactivity has been associated with several disease processes, including traumatic brain injury, subarachnoid hemorrhage, stroke,

carotid stenosis, and congestive heart failure.[52,53] Indeed, abnormal CO_2 vasoreactivity has been used as a means to prognosticate in some disease states.[53] Several studies have demonstrated that the cerebral vasculature adapts in the setting of chronically elevated $PaCO_2$ with changes in the pH of the brain extracellular fluid. This has obvious implications for the clinician attempting to treat raised ICP with chronic hyperventilation.

Arterial oxygen tension (PaO_2) also participates in the regulation of CBF. Arterial hypoxia dilates cerebral vessels at PaO_2 below 40 to 50 mm Hg. The relation between cerebral blood flow and arterial oxygen content is almost linear, and cerebral oxygen delivery can be maintained unless arterial oxygen content falls below 4 vol%. Hyperoxia does not appear to be a potent stimulus for vasoconstriction, however. The mechanisms of hypoxic vasodilation are not completely understood, but it is known that adenosine and both Ca2+-activated and ATP-activated potassium channels are particularly important. Adenosine, which leads to vasodilation through an increase in cAMP, has been found to increase by more than fivefold with hypoxia.[63]

A large body of evidence, both in animals and humans, implicates NO in a number of important processes within the cerebral circulation.[64-66] Vasodilation in response to acetylcholine, oxytocin, substance P, histamine, ET-1, ADP, ATP, and prostaglandin has all been shown to be NO dependent. Clinically, it is noteworthy that nitroprusside and other NO-donor compounds can dilate cerebral vessels.[67] This greatly complicates the management of hypertension in patients with increased intracranial pressure. In that setting, nitroprusside, for example, may reduce arterial pressure but raise both cerebral blood flow and blood volume, thereby causing herniation to occur. In addition, impaired NO signaling is important in the pathophysiology of subarachnoid hemorrhage where endothelial dysfunction has been well documented, leading to the important clinical problem of vasospasm.

ET-1 also mediates cerebrovascular tone.[68] Both ETA and ETB receptors have been identified in the cerebral vasculature. When given in high concentrations, ET-1 constricts cerebral vessels, probably via ETA receptor activation. In low concentrations, however, ET-1 relaxes cerebral vessels via endothelial cell ETB receptor activation, a response that is NO dependent. Sarafotoxin 6c (a selective ETB agonist) causes cerebral vasodilation. However, ETA and combined receptor antagonists do not alter basal cerebrovascular tone. Recently, ET-1 has been identified as an important mediator of vasospasm following subarachnoid hemorrhage. ET-1 levels are increased following subarachnoid hemorrhage. Associated with this increase, ETA receptor levels, smooth muscle cell ETB receptor levels (which mediate vasoconstriction), and endothelin-converting enzyme activity are increased. The potential clinical use of ET receptor antagonists following subarachnoid hemorrhage is under investigation, with promising preliminary results.[16]

Coronary Circulation

Right and left coronary arteries arise from sinuses of Valsalva and course over the surface of the heart. Nutrient branches penetrate the myocardium to supply both superficial (epicardial) and deep (subendocardial) layers of the muscle. Venous blood drains primarily to the coronary sinus, although some returns by way of

anterior coronary veins to the right atrium or via sinusoids directly to the ventricles.

Myocardial workload (which sets myocardial oxygen demand) is determined by not only the needs of the heart but also the demands of the body. Furthermore, the heart is required to generate its own perfusion pressure. Regulation of myocardial perfusion is, accordingly, tailored to match regional myocardial oxygen supply to demand over the widest possible range of cardiac workload and under conditions fashioned not so much for maximal cardiac efficiency but rather for benefit of the body.

Myocardial perfusion over a cardiac cycle is approximately the same per gram of tissue in the outer (subepicardial), mid, and inner (subendocardial) layers of the left ventricle, but the dynamics during the cardiac cycle are complicated. At the end of diastole, when the ventricle is relaxed and tissue pressures are generally under 10 mm Hg in any layer of the left ventricle, pressures in the intramural arteries are similar to each other and to aortic pressure. At the beginning of systole, tissue pressure rises to equal intracavitary pressure in the subendocardium but then falls off linearly across the wall to about 10 mm Hg in the subepicardium. These pressures are for an instant added to those inside the vessels because the vessels walls are not rigid. As a result, intravascular pressures in subendocardial arteries exceed aortic pressures, but aortic pressures are higher than pressures in subepicardial arteries. These pressure gradients and the greater shortening of subendocardial than subepicardial muscle fibers during systole compress the subendocardial vessels and squeeze blood out of them both forward into the coronary sinus and backward toward the epicardium. In fact, narrowing of the subendocardial vessels facilitates thickening and shortening of the myocytes.[69] This backflow enters the subepicardial arteries to supply their systolic flow. In systole, there is indeed some forward flow into the orifices of the coronary arteries, but this does not perfuse the myocardium; it merely fills the extramyocardial arteries.[70] In fact, there is often reverse flow in the epicardial coronary arteries. In early diastole, blood flows first into the subepicardial vessels that have not been compressed but takes longer to refill the narrowed subendocardial vessels. Given enough time and perfusing pressure, all the myocardium will be perfused, but if diastole is too short or perfusion pressure too low, subendocardial ischemia occurs. Right ventricular myocardium, on the other hand, is normally perfused in both systole and diastole (Fig. 26.13) because of lower tissue pressures. We would expect perfusion of the hypertrophied right ventricle of severe pulmonic stenosis or tetralogy of Fallot to resemble that of the left ventricle.[71]

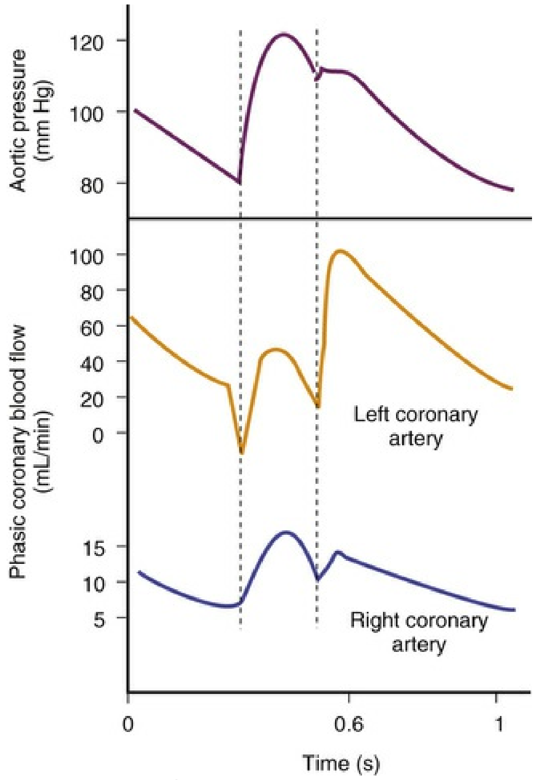

FIG. 26.13 Myocardial blood flow is modulated by ventricular wall tension. Most of the perfusion of the left ventricular myocardium occurs in diastole. (Adapted from Berne RM, Levy MN. Cardiovascular Physiology. 7th ed. St. Louis: Mosby; 1997.)

Myocardial Oxygen Demand-Supply Relationship

The left ventricle extracts most of the oxygen from the blood passing through the myocardium; coronary sinus oxygen saturation is normally about 30%. Therefore increases in myocardial oxygen demand have to be met by increases in myocardial blood flow. At rest, left ventricular myocardial blood flow is about 80 to 100 mL/100 g/min, and with maximal exertion, left ventricular oxygen consumption increases about fourfold, as does left ventricular blood flow in normal people and animals.[72] If coronary perfusion pressure does not change during exertion, the increased flow has to be achieved by a decrease in coronary vascular resistance; the response is termed *metabolic regulation.*

Coronary vascular resistance has three components: a basal low resistance in the arrested heart with maximally dilated vessels, an added resistance when vessels have tone, and a phasic resistance added whenever the ventricle contracts.[73] In the beating heart with vessels maximally dilated by a pharmacologic dilator, the second of these resistances is absent. Perfusion of the left ventricular myocardium then produces a steep pressure-flow relation that is linear at higher flows but usually curvilinear at low pressures and flows (Fig. 26.14A). Because the vessels are maximally dilated, flow is uncoupled from metabolism and depends only on driving pressure and resistance. If heart rate is increased, maximal flow at any perfusion pressure decreases because the heart is in a relaxed state for a smaller proportion of each minute.

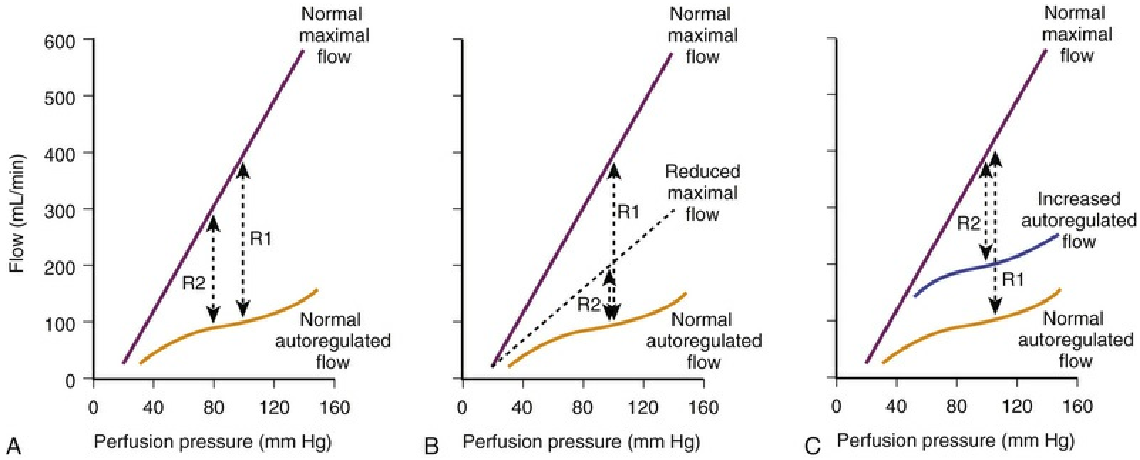

FIG. 26.14 (A) Normal pressure-flow relations in the left coronary artery during normal autoregulated flow and during maximal vasodilation. Values are appropriate for a left ventricle weighing approximately 100 g. R1, R2, coronary flow reserve measurements at two different coronary perfusing pressures. (B) Effect on coronary flow reserve of a reduced maximal flow. At the same coronary perfusing pressure, flow reserve is reduced from the normal R1 to R2. (C) Effect on coronary flow reserve of an increased autoregulated flow. Reserve is reduced from R1 to R2.

If tone is allowed to return to the coronary vessels, then the pressure-flow relationship can be assessed at different perfusion pressures after cannulating the left coronary artery. It is necessary to do this because when cardiac metabolism and blood flow are coupled, increasing aortic blood pressure will increase coronary flow not only by increasing perfusion pressure but also by increasing myocardial oxygen demand. Under normal conditions coronary blood flow is autoregulated, such that if perfusion pressure is raised or lowered from its normal value, there is a range over which there is almost no change in flow; a rise in pressure has caused vasoconstriction, and a fall in pressure has caused vasodilatation. At perfusion pressures above some upper limit, flow increases, probably because the pressure overcomes the constriction. More importantly, at pressures below about 40 mm Hg (but varying, as discussed later) flow decreases predominantly in the deep subendocardial muscle (see Fig. 26.14A), indicating that some vessels have reached maximal vasodilatation and can no longer decrease resistance to compensate for the decreased perfusion pressure. In these vessels, flow and pressure are directly related. If this pressure dependency occurs, then further decrease in perfusion pressure decreases local blood flow below its required amount, or if myocardial oxygen demands increase at the same low perfusion pressure (as will occur if the ventricle becomes dilated), the requisite increase in flow will not occur. These two conditions cause subendocardial ischemia.

At any given pressure, the difference between autoregulated and maximal flows is termed *coronary flow reserve*.[74-76] Coronary flow reserve can be measured in units of mL/min but can also be assessed by a dimensionless flow reserve ratio derived by dividing maximal flow by resting flow. Flow reserve depends on perfusion pressure because of the steepness of the pressure-flow relation in maximally dilated vessels. Coronary flow reserve indicates how much extra flow the myocardium can get at a given pressure to meet increased demands for oxygen; if reserve is much reduced, then flow cannot increase sufficiently to meet demands and myocardial ischemia

will occur. What the figure does not show is that coronary flow reserve is normally lower in the subendocardium than in the subepicardium and that decreases in coronary flow reserve are always more profound in the subendocardium than in the subepicardium.

If autoregulated flow is normal but maximal flow is decreased, as indicated by the decreased slope of the pressure-flow relation during maximal dilatation (Fig. 26.14B), then coronary flow reserve will be reduced. Such a change can occur with marked tachycardia; a decrease in the number of coronary vessels due to small vessel disease, as in some collagen vascular diseases, especially systemic lupus erythematosus; increased resistance to flow in one or more large coronary vessels because of embolism, thrombosis, atheroma, or spasm; impaired myocardial relaxation due to ischemia; myocardial edema; a marked increase in left ventricular diastolic pressure; marked increase in left ventricular systolic pressure if coronary perfusion pressure is not also increased, as in aortic stenosis or incompetence; and an increase in blood viscosity, most commonly seen with hematocrits over 65%.

Coronary flow reserve can also be reduced if maximal flows are normal but autoregulated flows increase (Fig. 26.14C). Increased myocardial flows above normal values can occur with exercise, tachycardia, anemia, carbon monoxide poisoning, leftward shift of the hemoglobin oxygen dissociation curve (as in infants with a high proportion of fetal hemoglobin), hypoxemia, thyrotoxicosis, acute ventricular dilatation (because of increased wall stress), inotropic stimulation by catecholamines, and acquired ventricular hypertrophy. When hypertrophy occurs a few months after birth, ventricular muscle mass increases without a concomitant increase in conducting coronary blood vessels. Ventricular hypertrophy returns wall stress to normal, and myocardial flow per minute per gram of muscle is approximately normal. Therefore total left ventricular flow is increased in proportion to ventricular mass, but because maximal flow per ventricle is usually unchanged, the coronary flow reserve is diminished. Often autoregulated flow is increased and maximal flows are reduced at the same time (eg, with severe tachycardia or cyanotic heart disease with hypoxemia, ventricular hypertrophy, and polycythemia). Under these circumstances, coronary flow reserve can be drastically reduced. A third mechanism that reduces coronary flow reserve is a shift to the right of the pressure-flow line. If with maximally dilated vessels, diastolic coronary flow is measured at different mean diastolic perfusion pressures, a pressure-flow line is obtained that is linear at higher pressures but curved in the low pressure-flow region.[77,78] Zero flow occurs at a pressure of about 8 to 12 mm Hg; this is the critical closing pressure that is above right atrial pressure.[79,80] The whole pressure-flow line can be shifted to the right by several factors, most important of which are pericardial tamponade, a rise in right or left ventricular diastolic pressures, and α-adrenergic stimulation. Such a rightward shift decreases flow reserve (Fig. 26.14D). It is important to note that because the line of maximal pressure-flow relations slopes up and to the right, any decrease in that slope (Fig. 26.14B), any increase in autoregulated flow (Fig. 26.14C), or any rightward shift of the slope (Fig. 26.14D) raises the pressure at which autoregulation fails to compensate for decreased perfusing pressure. It is also important to reemphasize that any decrease in coronary flow reserve affects the subendocardium predominantly, so autoregulation will fail first and ischemia occur in the subendocardium before these changes occur in the subepicardium.[81] The predominant reduction in subendocardial flow and reserve is particularly marked

when left ventricular diastolic pressure is high.

The interactions between myocardial blood flow and ventricular function are of particular importance when there is ventricular hypertrophy. Myocardial wall stress is regulated within a fairly narrow range, with or without myocardial hypertrophy. Consequently, myocardial blood flow per unit mass is fairly constant at about 1 mL/min/g of left ventricle at rest.[82-87] Strauer has shown a close relationship between peak wall stress in systole and the ratio of left ventricular mass to volume.[83,85,88,89] If there is no hypertrophy, coronary flow reserve is normal, but it is reduced if the left ventricular mass is increased. Should the heart dilate acutely, then the mass-to-volume ratio decreases, wall stress and myocardial oxygen consumption increase, and coronary flow reserve falls. If ventricular dilatation is marked, there can be subendocardial ischemia. Decreasing ventricular dilatation by afterload and preload reduction reverses these unfavorable events and is another reason for the resulting improvement in ventricular function.

Right ventricular myocardial blood flow follows the general principles regarding coronary blood flow, but there are differences related to the low right ventricular systolic pressure and to the fact that alterations in aortic pressure change coronary perfusing pressure without altering right ventricular pressure work. If the normal right ventricle is acutely distended, for example, by pulmonary embolism, there will eventually be right ventricular failure; the increased wall stress increases its oxygen consumption, but the raised systolic pressure reduces the coronary flow, so when supply cannot match demand there will be right ventricular myocardial ischemia.[90] Raising aortic perfusing pressure mechanically or with α-adrenergic agonists increases right ventricular myocardial blood flow, relieves ischemia, and restores right ventricular function to normal. Improved coronary flow is not the only mechanism of this improvement; the increased left ventricular afterload moves the ventricular septum toward the right ventricle and improves left ventricular performance.[91] If right ventricular pressure is chronically elevated so that there is right ventricular hypertrophy, as in pulmonic stenosis, many forms of cyanotic congenital heart disease, and some chronic lung diseases, then right ventricular myocardial blood flow behaves in the same way as left ventricular blood flow, with one exception.[92-94] If aortic pressure is lowered, left ventricular pressure also decreases, as do left ventricular work and oxygen consumption. In the right ventricle, however, the workload may not be reduced (if there is no ventricular septal defect), so an imbalance between myocardial oxygen supply and demand may occur. The worst imbalance occurs when aortic systolic pressure is maintained but coronary perfusing pressure decreases, and this can occur in a child with tetralogy of Fallot who has too large an aortopulmonary anastomosis. The high aortic and left ventricular systolic pressures mandate an equally high right ventricular systolic pressure, but the low diastolic aortic pressure reduces coronary perfusion pressure in diastole and can cause both left and right ventricular ischemia and failure.[95]

Gastrointestinal Circulation

The maintenance of adequate splanchnic blood flow in critically ill patients is important. In a globally compromised circulation, the gastrointestinal system is particularly prone to injury, impairing its two chief functions: the digestion and absorption of nutrients and the maintenance of a barrier to the translocation of enteric antigens.[96-98] Moreover, splanchnic ischemia has been associated with

multiple organ failure and increased morbidity and mortality in these patients.[99,100]

The gastrointestinal circulation has multiple levels of regulation. Broadly, these can be divided into intrinsic and extrinsic mechanisms. Intrinsic mechanisms include local metabolic processes, locally produced vasoactive substances, and myogenic reflexes. Extrinsic factors include circulating vasoactive substances, neural innervation, and general hemodynamic forces.[102] Neural input arising from the medulla oblongata through preganglionic fibers of the intermediolateral area of the spinal cord participates in the regulation of large blood vessels (>50 μm), largely through sympathetic α-adrenergic control. Blood flow to the intestinal circulation, like other vascular beds, is autoregulated such that oxygen delivery remains fairly constant with inflow pressures varying from 30 to 120 mm Hg.[102] Oxygen, carbon dioxide, H+ ions, and adenosine are important local metabolic mediators of this process. Other important vasoactive mediators of intestinal blood flow include serotonin, histamine, bradykinin, and prostaglandin, although their role in autoregulation is unclear.[103,104] Finally, various gastrointestinal hormones and peptides released from the intestinal mucosa and intestinal glands including gastrin, vasoactive intestinal polypeptide, cholecystokinin, secretin, glucagon, enkephalins, somatostatin, and kallidin are known to have vasoactive properties.[101]

A phenomenon unique to the gastrointestinal circulation is the increase in flow following the consumption of nutrients. This postprandial intestinal hyperemia appears to involve multiple factors. However, the composition of the chyme is particularly important. In fact, luminal distention, mechanical stimulation, and extrinsic neural stimulation are not necessary for the response to occur.[101] Lipids in combination with bile salts are the most potent triggers for postprandial hyperemia. Glucose is the most potent single stimulus for this response. Blood flow to skin and skeletal muscle decreases and cardiac output increases during postprandial hyperemia. Furthermore, nutrients that induce the largest increase in blood flow elicit the largest oxygen debt within the intestinal villi.

Interestingly, this postprandial hyperemia may be protective in some instances of low blood flow to the intestinal mucosa. Glucose has been shown to ameliorate mucosal ischemia in models of septic and hemorrhagic shock, and early enteral feeding has been advocated in human studies as well.[105] Conversely, enteral feeding has also been associated with bowel ischemia and injury in some patients, such as premature infants, thus complicating decisions around enteral feeding during or following low-flow states.[106]

Increasing data demonstrate a large role for NO in the regulation of gastrointestinal blood flow. NO, at least in part, mediates basal mesenteric and hepatic blood flow. Indeed, a number of studies implicate endothelial dysfunction, and aberrations in NO signaling in particular, in portal hypertension and cirrhosis.[107-109] NO also participates in the maintenance of the mucosal barrier function and is further protective by virtue of its inhibitory effect on platelet and leukocyte adhesion.[110] Furthermore, postprandial hyperemia has been shown to involve adenosine-mediated NO release.[111] Finally, neuronal NO synthase (nNOS) and inducible NO synthase (iNOS) are important in both normal and abnormal gastrointestinal motility and gastrointestinal inflammatory disorders, respectively.[112-114]

ET-1 is another important mediator of intestinal blood flow. The intestinal vasculature displays increased vasoconstriction in response to ET-1 compared with

other vascular beds. This has particular importance for gastrointestinal blood flow in critically ill patients as ET-1 levels have been found to be elevated following surgery and in association with a number of disease states, including hypoxia, pancreatitis, and sepsis. ET receptor antagonism ameliorates ischemic injury to the bowel in several models of low-flow states.[115,116]

Finally, it should be remembered that drugs used to augment systolic blood pressure and/or to enhance cardiac output could have various effects on the gastrointestinal circulation. Fenoldopam, a dopamine-1 receptor agonist, has been shown to improve intestinal perfusion during hemorrhage.[117] Findings on more common agents such as norepinephrine, dopamine, and vasopressin, however, have had mixed results depending on the doses used and the models or clinical situations studied.[118-120] Thus investigations continue to target the determination of an optimum strategy to improve overall cardiac output and oxygen delivery without compromising flow to specific organs, such as the bowel.

Renal Circulation

Blood flow to the kidneys greatly exceeds the metabolic needs of the organs themselves. In a 70-kg adult, combined renal blood flow is approximately 1200 mL/min, accounting for just over 20% of total cardiac output supplying organs that represent under 0.5% of total body weight.[121] This high renal blood flow is necessary in order to support glomerular filtration, such that solute and fluid homeostasis can be maintained.

Blood is supplied to the kidneys by the renal arteries, which branch to form the interlobar, arcuate, and interlobular arteries. Interlobular arteries progress to form the afferent arterioles, which lead to the glomerular capillaries within the glomerulus, the site of fluid and solute filtration. The distal glomerular capillaries reform into the efferent arterioles, which then lead to a second capillary system, the peritubular capillaries. An elevated hydrostatic pressure within the glomerular capillaries supports filtration, whereas a much lower pressure within the peritubular capillary system supports absorption.[121] Alterations in the resistance of the afferent and efferent arterioles regulate these pressures and allow for dynamic changes in renal function in response to overall fluid and solute needs.

Renal blood flow is determined by the difference between renal artery pressure (which is generally equivalent to systemic arterial pressure) and renal vein pressure, over the renal vascular resistance. In general, three vascular segments limit renal vascular resistance: the interlobular arteries, afferent arterioles, and efferent arterioles. Regulation of renal vascular resistance can be broadly divided into extrinsic mechanisms and intrinsic mechanisms. Extrinsic mechanisms, which include the sympathoadrenal system, atrial natriuretic system, and renin-angiotensin-aldosterone axis, modulate renal blood flow by alterations in intrarenal vascular tone, mesangial tone, intravascular volume, and systemic vascular resistance.[121] Intrinsic mechanisms, which primarily alter afferent arteriolar resistance, are responsible for the autoregulation of renal blood flow in response to changes in renal perfusion pressure.

The juxtaglomerular apparatus, which includes the afferent and efferent arterioles, macula densa, and glomerular mesangium, is an important site in the regulation of renal perfusion and glomerular filtration. Glomerular filtration is largely a function of glomerular filtration pressure, which in turn is dependent on renal perfusion

pressure and, importantly, the balance between afferent arteriolar and efferent arteriolar tone. Increased efferent arteriolar tone increases glomerular filtration by increasing glomerular pressure, whereas increased afferent arteriolar tone has the opposite effect.

Endogenous epinephrine and norepinephrine derived from sympathetic neural input have various effects on renal perfusion and glomerular filtration. Mild sympathetic output preferentially constricts the efferent arterioles, thereby increasing glomerular pressure and filtration.[122] However, intense sympathetic discharge results in afferent arteriolar constriction, which decreases glomerular filtration. Furthermore, sympathetic stimulation of afferent arterioles results in renin release, which leads to increased sodium reabsorption and fluid retention. Sympathetic stimulation can affect renal blood flow more generally by alterations in systemic arterial pressure. Indeed, clinically norepinephrine has been shown to increase renal perfusion and renal function (measured by changes in creatinine clearance) in patients with septic shock.

Angiotensin II, produced by cleavage of angiotensin I by the enzyme angiotensin-converting enzyme (ACE), also has important effects on renal perfusion. Like catecholamine stimulation, the effects of angiotensin II are dose related. At low levels, angiotensin II results in efferent arteriolar constriction, whereas at high levels both the afferent and efferent arterioles are constricted.[122] Angiotensin II alters renal blood flow further by alterations in intravascular volume through aldosterone and arginine vasopressin and by increasing systemic vascular resistance.

Arginine vasopressin (AVP) is synthesized in the anterior hypothalamus and released from the posterior pituitary gland. It plays a critical role in maintaining serum osmolality within a narrow range. Both V1 and V2 receptors have been identified. V2 receptors are located on the renal collecting ducts, and stimulation results in increased reabsorption of water. Activation of V1 receptors on systemic vessels results in vasoconstriction. Interestingly, V1 receptor activation in the pulmonary vasculature results in vasodilation, at least in part via NO production. Triggers for AVP release include changes in serum osmolality, hypovolemia, and hypotension. Patients with septic shock have been shown to have decreased levels of AVP, which has led to the use of AVP supplementation clinically. Unlike catecholamines and angiotensin II, high levels of AVP appear to preferentially constrict efferent arterioles, which preserves glomerular filtration.

ET-1 has diverse effects on the kidney.[123] In general, endothelin results in vasoconstriction, decreased renal perfusion, and decreased glomerular filtration. ET-1 constricts both the afferent and efferent arterioles. ET-1 has also been shown to stimulate cell proliferation within the kidney. Conversely, ET-1 may also promote natriuresis through ETB-receptor activation. Furthermore, alterations in ET-1 signaling have been implicated in a host of renal diseases including acute and chronic renal failure, essential hypertension, glomerulonephritis, renal fibrosis, and renal transplant rejection.[123]

Important vasodilators within the renal circulation include prostaglandins and atrial natriuretic peptide (ANP). The vasodilating prostaglandins (D2, E2, and I2) are synthesized from arachidonic acid by the enzyme phospholipase A2. Most of the important vasoconstricting factors, such as catecholamines, angiotensin II, and AVP, stimulate the release of prostaglandins, promoting increased renal perfusion and glomerular filtration. ANP is produced within the atrial myocytes and is released in

response to increased atrial stretch. Through cGMP signaling, ANP results in afferent arteriolar dilation and increased renal perfusion and glomerular filtration. ANP also antagonizes the actions of endogenous catecholamines, angiotensin II, and AVP.

Like other organ systems, renal blood flow is autoregulated via mechanisms intrinsic to the renal vasculature.[121] Early studies demonstrate that renal blood flow and glomerular filtration remain constant at renal artery perfusion pressures of between 80 and 180 mm Hg.[124] Importantly, urinary flow rate is not constant within the autoregulatory range but rather changes as a function of renal perfusion pressure. The precise mechanisms underpinning this autoregulation are unclear. However, recent evidence indicates that the mechanisms are likely complex involving interactions between tubuloglomerular feedback and myogenic processes that protect the kidney from damage in the setting of hypertension and also regulate renal function.[125-127]

A number of disease states that affect critically ill patients result in the loss of renal autoregulation. Acute tubular necrosis, septic shock, hepatic failure, and cardiopulmonary bypass have all been associated with renal dysfunction and a loss of renal autoregulation.

Conflicting Needs of Regional Circulations

The regional circulations maintain homeostasis independently and in concert. This is natural because individual organs have their own needs. Yet each region also has a responsibility to the body as a whole. There are times when individual need and responsibility conflict. Life-threatening illness accentuates these "conflicts of interest." An example follows:

The pulmonary and cerebral circulations respond differently to acute respiratory alkalosis. Alkalosis lowers pulmonary vascular resistance, but hypocarbia promotes vasoconstriction of the cerebral vasculature. The diametric behavior of these two circulations presents a challenge to clinicians managing patients following caval-pulmonary anastomosis for palliation of single ventricle congenital heart disease. With this anatomy, pulmonary blood flow is dependent on passive venous return (without a subpulmonary ventricle) from the superior vena cava (SVC). Pulmonary blood flow can be impaired if pulmonary vascular resistance increases. However, hyperventilation to decrease pulmonary vascular resistance actually decreases pulmonary blood flow if the resultant hypocarbia diminishes cerebral blood flow (due to cerebral vascular vasoconstriction) and SVC blood flow. This may result in a net decrease in pulmonary blood flow and desaturation.

It is possible that unsuccessful arbitration among regional circulations contributes to the genesis of the syndrome of multiple organ system failure (see Chapter 112). An increasing understanding of the mechanisms that regulate regional, microcirculatory blood flow will lead to new and improved treatments that optimize blood flow and allow the intensivist to successfully arbitrate the regional blood flow "conflict of interests" that will best serve the short- and long-term interests of the critically ill children.

CHAPTER 27

Endothelium and Endotheliopathy

Yves Ouellette

PEARLS

- Because of their location, endothelial cells have the ability to interact with blood components, such as flow, soluble factors, and other cells. Endothelial cells integrate these signals into a cohesive regulation of vascular responses.
- The endothelium controls the vascular tone of the underlying smooth muscle cells through the production of vasodilator and vasoconstrictor mediators.
- Endothelial cell activation in response to inflammation changes endothelial cellular physiology and alters vascular function.
- A large number of endothelial cell–active molecules are potential biomarkers for the early diagnosis of sepsis.

Until recently, scientists and clinicians considered the endothelium, the cell layer that lines the blood vessels, as an inert barrier separating the various components of blood and the surrounding tissues. The vascular endothelium is now recognized as a highly specialized and metabolically active organ performing a number of critical physiologic, immunologic, and synthetic functions. These functions include regulation of vascular permeability, fluid and solute exchange between the blood and interstitial space, vascular tone, cell adhesion, homeostasis, and vasculogenesis.[1]

The normal vascular endothelium is only one cell layer thick, separating the blood and vascular smooth muscle. The endothelium responds to physical and biochemical stimuli by releasing regulatory substances affecting vascular tone and growth, thrombosis and thrombolysis, and platelet and leukocyte interactions with the endothelium. Normal endothelial functions include control over thrombosis and thrombolysis, platelet and leukocyte interactions with the vessel wall, and regulation of vascular tone and growth. Of particular interest to intensivists is the fact that the endothelium secretes both powerful vasorelaxing (eg, nitric oxide [NO]) and vasoconstricting substances (eg, endothelin-1 [ET-1]). Because normal endothelial function plays a central role in vascular homeostasis, it is logical to conclude that endothelial dysfunction contributes to disease states characterized by vasomotor

dysfunction, abnormal thrombosis, or abnormal vascular proliferation.

The endothelium lies between the lumen and the vascular smooth muscle, where it is uniquely positioned to "sense" changes in hemodynamic forces or blood-borne signals by membrane receptor mechanisms. The endothelial cells can respond to physical and chemical stimuli by synthesis or release of a variety of vasoactive and thromboregulatory molecules and growth factors.

The vascular endothelium possesses numerous enzymes, receptors, and transduction molecules, and it interacts with other vessel wall constituents and circulating blood cells. In addition to these universal functions, the endothelium may have organ-specific roles that are differentiated for various parts of the body, such as gas exchange in the lungs, control of myocardial function in the heart, or phagocytosis in the liver and spleen.

Normal Endothelial Function

Endothelial Cell Heterogeneity

Many vascular diseases appear to be restricted to specific vascular beds. For example, thrombotic events are often localized to single vessels. It is also common for certain vasculitides to specifically affect certain arteries, veins, or capillaries or to affect certain organs. Tumor cells often metastasize more commonly within particular vascular beds. The basis for this variability in vascular disease is poorly understood but may be explained by the heterogeneity of endothelial cells. There has been a greater understanding of how endothelial cell heterogeneity may contribute both to the maintenance of organ-specific function and to the development of disorders restricted to specific vascular beds.[1-3]

The morphologic appearance of capillary endothelium from different vascular beds may explain differences in tissue function. For example, the brain microcirculation is lined by endothelial cells connected by tight junctions that maintain the blood-brain barrier. By contrast, sinusoids found in the liver, spleen, and bone marrow are lined by endothelial cells that allow transcellular trafficking between intercellular gaps. Similarly, fenestrated endothelial cells found in the intestinal villi, endocrine glands, and kidneys facilitate selective permeability, which is required for efficient absorption, secretion, and filtering.[4]

Another example of endothelial cell heterogeneity lies in the expression of cell surface receptors involved in cell-to-cell signaling and cell trafficking. For example, in the mouse, lung-specific endothelial cell adhesion molecules are exclusively expressed by pulmonary postcapillary endothelial cells and some splenic venules. Similarly, specific mucosal cell adhesion molecules are expressed primarily on endothelial venules in the Peyer patches of the small intestine.[5,6] Tumor cells may show clear preferential adhesion to the endothelium of specific organs paralleling their in vivo metastatic propensities.[7] Distinct subsets of endothelial cells often exist within a single organ. During in situ studies, two distinct sinusoidal endothelial cell phenotypes can be recognized in the adult human liver: Hepatic periportal vessels express specific cell surface molecules such as PECAM-1 and CD34, whereas sinusoidal intrahepatic endothelial cells do not.

Endothelial Progenitor Cells

A significant amount of literature has shown that maintenance and repair of vasculature in ischemic diseases may be at least partially mediated through recruitment of endothelial progenitor cells (EPCs) from the bone marrow to areas of vascular injury.

An EPC is a specific subtype of hematopoietic stem cell that has been isolated from circulating mononuclear cells, bone marrow, and cord blood. EPCs migrate from the bone marrow to the peripheral circulation, where they contribute to vascular repair.[8,9] When injected into animal models of ischemia, EPCs are incorporated into sites of neovascularization[8,10,11] and have contributed to improved outcomes in patients with ischemic vascular disorders.[12] In addition, there has been accumulating evidence for the function of EPCs in critical illnesses such as sepsis.

Recruitment of EPCs to areas of endothelial and vascular damage may have prognostic implications and be associated with clinical outcome. The pathophysiologic changes associated with critical illness, notably sepsis and sepsis-related organ dysfunction, may lead to apoptosis and necrosis of endothelial cells from the vasculature and recruitment of EPCs from the bone marrow.

In various models of vascular injury and organ dysfunction, only a few studies have emerged regarding EPCs in particular as a therapeutic strategy. Transplanted EPCs have been shown to improve survival of mice following liver injury.[13] Infusion of EPCs also restored blood flow in a mouse model of hind limb ischemia.[9] A prospective randomized trial compared the effects of EPC transplantation in patients with idiopathic pulmonary arterial hypertension versus conventional therapy and showed that after 12 weeks, patients who had received EPCs had a significant improvement in their 6-minute walk test, mean pulmonary artery pressure, pulmonary vascular resistance, and cardiac output.[14]

Coagulation and Fibrinolysis

A normal physiologic function of the endothelium is to provide an antithrombotic surface inhibiting platelet adhesion and clotting, thus facilitating normal blood flow. Under pathophysiologic conditions, the endothelium transforms into a prothrombotic surface. A dynamic equilibrium exists between both states that permits a rapid response to an insult and a rapid recovery.[15]

Anticoagulant Mechanisms

The endothelium has anticoagulant, antiplatelet, and fibrinolytic properties.[16] Endothelial cells are the major sites for anticoagulant reactions involving thrombin. Thrombin plays a key role in coagulation, including the activation of platelets, activation of several coagulation enzymes and cofactors, and stimulation of procoagulation pathways on the endothelial cell surface. In the normal state, there is little thrombin enzyme activity. The surrounding endothelial cell matrix contains heparin sulfate and related glycosaminoglycans that activate antithrombin III. In addition, the subendothelial cell matrix contains dermatan sulfate, which promotes the antithrombin activity of heparin cofactor II. Furthermore, microvascular endothelial cells release a tissue factor pathway inhibitor that inhibits the factor VIIa/tissue factor complex and further contributes to anticoagulation (Fig. 27.1).

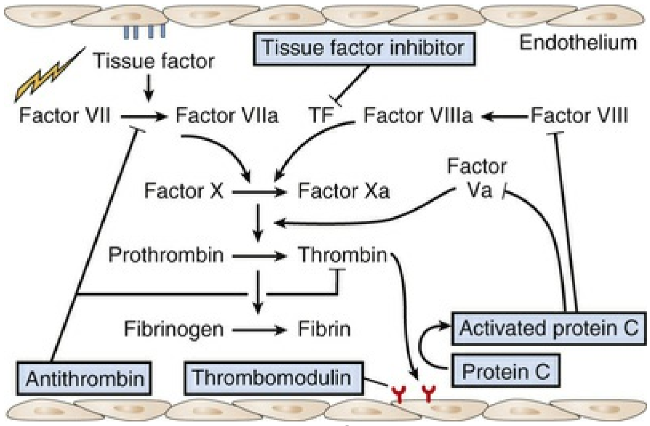

FIG. 27.1 Endothelium control of the coagulation cascade. An inflammatory stimulus up-regulates the interaction of tissue factor (TF) with factor VII, which generates activated factor VII (factor VIIa). The TF–factor VIIa complex then leads to the conversion of factor X to factor Xa. The interaction of factors Xa and Va results in the conversion of prothrombin to thrombin and the conversion of fibrinogen to fibrin. Three key anticoagulant pathways can inhibit this process. Protein C is activated through its interaction with cell-surface thrombomodulin and inhibits the activities of factors Va and VIIIa. Antithrombin blocks the activation of multiple factors including factor X and thrombin. Tissue factor pathway inhibitor interferes directly with the tissue factor–factor VIIa complex.

Thrombin activity is also modulated by endothelial cell synthesis of thrombomodulin.[17,18] The binding of thrombin to thrombomodulin facilitates the enzyme's activation of the anticoagulant protein C. Activated protein C (APC) activity is enhanced by cofactor C, also called protein S, which is synthesized by endothelial cells as well as by other cells (see Fig. 27.1). APC inhibits factor Va and factor VIIIa. Thrombomodulin (TM) also inhibits prothrombinase activity indirectly by binding factor Xa (Fig. 27.2). Protein C has a special receptor on the endothelial cells: endothelial protein C receptor (EPCR). EPCR augments protein C activation approximately 20-fold in vivo by binding protein C and presenting it to the thrombin-TM activation complex. Both EPCR and TM can be found in plasma as soluble proteins. Activated protein C retains its ability to bind EPCR, and this complex appears to be involved in some of the cellular signaling mechanisms that down-regulate inflammatory cytokine formation (tumor necrosis factor, interleukin-6). In addition, platelet adhesion to endothelial cells is markedly inhibited by endothelium-derived prostacyclin.[19] The same stimuli that activate platelets, such as thrombin and adenosine diphosphate and adenosine triphosphate (ATP), also act to release prostacyclin from the endothelium, which allows the endothelium to limit the extent of platelet plug formation. The interactions between platelets and endothelium regulate platelet function, coagulation cascades, and local vascular tone.

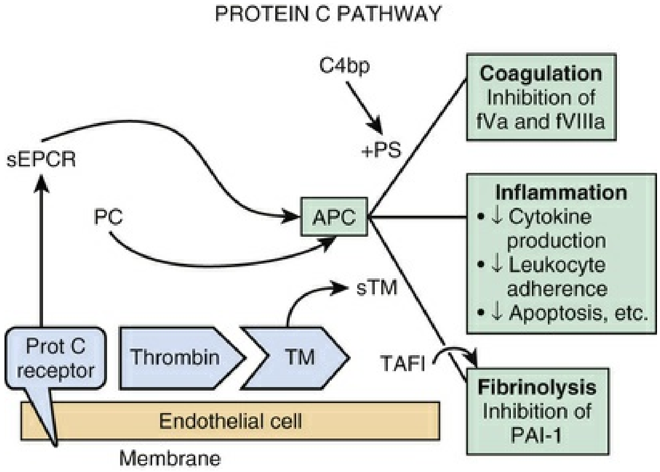

FIG. 27.2 The interaction of the protein C system with the endothelium: Thrombin bound to thrombomodulin (TM) modifies protein C bound to the endothelial protein C receptor on the cell surface to generate activated protein C (APC). APC acts as a natural anticoagulant by inactivating activated factors V (fVa) and VIII (fVIIIa), modulating inflammation by down-regulating the synthesis of proinflammatory cytokines, leukocyte adherence, and apoptosis and enhancing fibrinolysis by inhibiting thrombin-activatable fibrinolysis inhibitor (TAFI) and plasminogen activator inhibitor type-1 (PAI-1). *C4Bbp,* C4b binding protein (binds protein S); *+PS*, in the presence of protein S; *sEPCR*, soluble endothelial cell protein C receptor; *sTM*, soluble thrombomodulin. (Modified from Hazelzet J. Pathophysiology of pediatric sepsis. In: Nadel S. Infectious Diseases in the Pediatric Intensive Care Unit. London: Springer; 2008.)

Microvascular endothelial cells may secrete tissue-type plasminogen activator (t-PA), the powerful thrombolytic agent in frequent clinical use for treatment of coronary thrombotic occlusion.[20] t-PA release is stimulated in vivo by norepinephrine, vasopressin, or stasis within the vessel lumen. Thrombin may also stimulate t-PA release, providing a further endothelium-mediated safeguard against uncontrolled coagulation.

Procoagulant Mechanisms

The expression and release of tissue factor is the pivotal step in transforming the endothelium from an anticoagulant to a procoagulant surface.[21,22] Tissue factor accelerates factor VIIa-dependent activation of factors X and IX (see Fig. 27.1). The synthesis of tissue factor is induced by a number of agonists, including thrombin, endotoxin, several cytokines, shear stress, hypoxia, oxidized lipoproteins, and other endothelial insults. Once endothelial cells expressing tissue factor are exposed to plasma, prothrombinase activity is generated and fibrin is formed on the surface of the cells. Tissue factor can also be found in plasma as a soluble protein. Its role there is not well understood, but it probably plays a role in the initiation of coagulation.

Endothelium-Derived Vasodilators

The important role that the endothelium plays in controlling vascular tone has only recently been appreciated. Clinicians and researchers have come to appreciate that the endothelium controls underlying smooth muscle tone in response to certain

pharmacologic and physiologic stimuli. This response involves a number of luminal membrane receptors and complex intracellular pathways and the synthesis and release of a variety of relaxing and constricting substances, described in the following sections.

Nitric Oxide

Furchgott and Zawadzki first postulated the existence of an endothelial-derived relaxing factor (EDRF) in 1980, when they noticed that the presence of endothelium was essential for rabbit aortic rings to relax in response to acetylcholine.[21] Later it was determined that the biological effects of EDRF are mediated by NO.[23]

NO is generated from the conversion of L-arginine to NO and L-citrulline by the enzyme nitric oxide synthase (NOS).[24] There are two general forms of NOS: constitutive and inducible. In the unstimulated state, NO is continuously produced by constitutive NO synthase (cNOS). The activity of cNOS is modulated by calcium that is released from endoplasmic stores in response to the activation of certain receptors. Substances such as acetylcholine, bradykinin, histamine, insulin, and substance P stimulate NO production through this mechanism. Similarly, shearing forces acting on the endothelium are another important mechanism regulating the release of NO. The inducible form of NOS (iNOS) is not calcium dependent but instead is stimulated by the actions of cytokines (eg, tumor necrosis factor-α [TNFα], interleukins) or bacterial endotoxins (eg, lipopolysaccharide). Induction of iNOS occurs over several hours and results in NO production that may be more than a thousandfold greater than that produced by cNOS. This is an important mechanism in the pathogenesis of inflammation (see Fig. 27.2). Inhibition of NOS using competitive analogs of L-arginine drastically reduces endothelium-dependent relaxation in vitro, particularly in large conduit arteries, thereby evoking vasoconstriction. Chronic treatment of animals with NOS inhibitors or suppression of the cNOS gene is reported to induce hypertension.[25-27]

Once NO is formed by an endothelial cell, it readily diffuses out of the cell and into adjacent smooth muscle cells where it binds and activates the soluble form of guanylyl cyclase, resulting in the production of cyclic guanosine-monophosphate (cGMP) from guanosine-triphosphate.[28] cGMP in turn activates a number of cGMP-modulated enzymes (Fig. 27.3). Increased cGMP activates a kinase that subsequently leads to the inhibition of calcium influx into the smooth muscle cell and decreased calcium-calmodulin stimulation of myosin light chain kinase. This, in turn, decreases the phosphorylation of myosin light chains, thereby decreasing smooth muscle tension development and causing vasodilation. There is also some evidence that increases in cGMP can lead to myosin light chain dephosphorylation by activating the phosphatase. In addition, cGMP-dependent protein kinase phosphorylates K^+ channels to induce hyperpolarization and thereby inhibits vasoconstriction.[29,30] Interestingly, NO inhibition of platelet aggregation is also related to the increase in cGMP. Drugs that inhibit the breakdown of cGMP such as inhibitors of cGMP-dependent phosphodiesterase (eg, sildenafil) potentiate the effects of NO-mediated actions on the target cell.

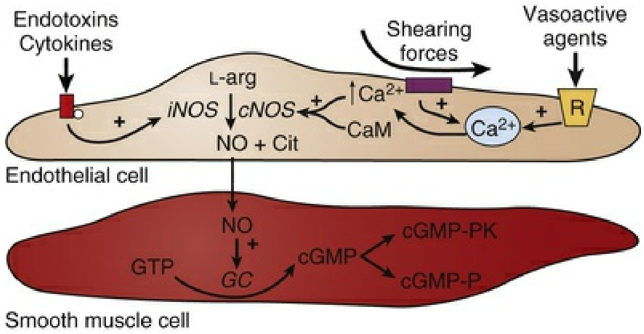

FIG. 27.3 Nitric oxide (NO) is generated from L-arginine (L-arg) by the action of nitric oxide synthase (NOS). In the resting state, constitutive NOS (cNOS) is modulated by intracellular Ca^{2+} and calmodulin (CaM). Stored Ca^{2+} is released in response to vasoactive agents (acetylcholine and bradykinin, for example) and other external stimuli such as shearing forces. Activation of endothelial cells by cytokines and endotoxins increases expression of inducible NOS (iNOS). Citrulline (Cit) is a byproduct of NO production. NO has a half-life of only a few seconds in vivo and quickly diffuses to surrounding cells such as smooth muscle cells. NO stimulates the production of the intracellular mediator cyclic GMP (cGMP). Increased cGMP activates a series of cGMP-dependent protein kinases (cGMP-PKs) and cGMP-dependent phosphatases (cGMP-Ps).

NO therefore contributes to the balance between vasodilator and vasoconstrictor influences that determine vascular tone.[31]

Prostacyclin

Another major endothelium-derived vasodilator is the prostaglandin prostacyclin (PGI_2), a derivative of arachidonic acid synthesized through the action of the enzyme cyclooxygenase. Endothelium cells are capable of producing a variety of vasoactive substances that are products of arachidonic acid metabolism. Among these are prostaglandins, PGI_2, leukotrienes, and thromboxanes. These substances act as either vasodilators or vasoconstrictors, among their other biological activities. PGI_2 is a potent vasodilator and is active in both the pulmonary and systemic circulations. In addition to its vasodilatory effects, prostacyclin also has antithrombotic and antiplatelet activity. Its release may be stimulated by bradykinin and adenine nucleotides. Like NO, it is chemically unstable with a short half-life.[32] However, unlike NO, PGI_2 activity in arterial beds depends on its ability to bind to specific receptors in vascular smooth muscle. Its vasodilator activity is therefore determined by the expression of such receptors. PGI_2 receptors are coupled to adenylate cyclase to elevate cyclic AMP levels in vascular smooth muscle.[33] The increase in cAMP results in (1) stimulation of ATP-sensitive K^+ channels resulting in hyperpolarization of the cell membrane and inhibition of the development of contraction and (2) increased efflux of Ca^{2+} from the smooth muscle cell and inhibition of the contractile machinery.

In addition, PGI_2 facilitates the release of NO by endothelial cells, and NO potentiates the action of PGI_2 in vascular smooth muscle. Interestingly, NO may also potentiate the effects of prostacyclin. The NO-mediated increase in cGMP in smooth

muscle cells inhibits a phosphodiesterase that breaks down cAMP and therefore indirectly prolongs the half-life of the second messenger of PGI_2.[34]

Endothelium-Derived Hyperpolarizing Factor

Endothelium stimulation by acetylcholine also produces hyperpolarization of the underlying smooth muscle and thereby induces vasorelaxation. This process is not mediated by NO but is instead mediated by another endothelium-derived factor. This factor increases K^+-channel conductance in smooth muscle cells, resulting in smooth muscle cell relaxation. The resulting vasodilation is not inhibited by L-NMMA, the specific antagonist of NO, but is inhibited by ouabain, a Na^+/K^+-ATPase inhibitor. In addition, in most medium- to resistance-sized arteries, electrophysiologic studies have established that endothelium-dependent hyperpolarization of vascular smooth muscle is resistant to the combined inhibition of both NOs and cyclooxygenases. Accordingly, a component of the endothelium-dependent relaxation in these arteries is mediated by a substance different from NO and PGI_2. This component of endothelium-dependent vasodilatation has been attributed to a yet unidentified diffusible endothelium-derived hyperpolarizing factor (EDHF).[35]

Of significant clinical importance is the fact that EDHF-mediated effect increases as the arterial diameter decreases, such as in resistance arteries. EDHF likely plays a significant role in the regulation of peripheral vascular resistance and local hemodynamics. Unfortunately, in the absence of selective inhibitors of the EDHF pathway, it is not possible to evaluate the relevance of EDHF in vivo.[35]

Endothelium-Derived Vasoconstrictors

Endothelins (Endothelium-Derived Contracting Factors)

Endothelin is a 21-amino-acid peptide and is one of the most potent vasoconstrictors yet identified. Endothelial cells synthesize the prohormone big endothelin and express endothelin-converting enzymes to generate endothelin. There are three isoforms of endothelin, but only one (ET-1) has been shown to be released from human endothelial cells. ET-1 is synthesized in the endothelial cells and its release is mediated by a variety of stimuli. ET-1 release is stimulated by angiotensin II, antidiuretic hormone, thrombin, cytokines, reactive oxygen species, and shearing forces acting on the vascular endothelium. ET-1 release is inhibited by nitric oxide as well as by PGI_2 and atrial natriuretic peptide.[36,37]

ET-1 has a short half-life, suggesting that similarly to NO, ET-1 is mainly a locally active vasoregulator. Once released by endothelial cells, ET-1 binds to a membrane receptor (ET_A) found on adjacent vascular smooth muscle cells. This binding leads to calcium mobilization and smooth muscle contraction. The ET_A receptor is coupled with a G-protein linked to phospholipase-C, resulting in the formation of IP_3. Interestingly, ET-1 can also bind to an ET_B receptor located on the vascular endothelium, which stimulates the formation of NO by the endothelium. This release of NO appears to modulate the ET_A receptor-mediated contraction of the vascular smooth muscle. Its physiologic role includes maintenance of basal vascular resistance, and it is present in healthy subjects in low concentrations.

Reactive Oxygen Species

Endothelial cells secrete oxygen-derived free radicals and hydrogen peroxide in response to shear stress and endothelial agonists like bradykinin. Such reactive oxygen species are reported to inactivate NO, resulting in vasoconstriction. Reactive oxygen species may also facilitate the mobilization of cytosolic Ca^{2+} in vascular smooth muscle cells and promote Ca^{2+} sensitization of the contractile elements. Under conditions of hyperoxia, endothelium-derived superoxide anion may combine with NO with diffusion-limited kinetics to generate peroxynitrite, negating NO-mediated vasodilation, an effect inhibited by superoxide dismutase, which metabolizes superoxide anion to hydrogen peroxide.[38]

Vasoconstrictor Prostaglandins

The metabolism of arachidonic acid by cyclooxygenase in endothelial cells may lead to the secretion of precursors of thromboxanes and leukotrienes. These prostaglandins act on receptors in vascular smooth muscle to induce vasoconstriction. PGI_2, however, is the major endothelial metabolite of arachidonic acid that is generated through the cyclooxygenase pathway. Thus under normal circumstances, the influence of the small amounts of vasoconstrictor prostanoids released by endothelial cells is masked by the production of PGI_2, NO, and EDHF.[39,40]

Endothelium and Blood Cell Interactions

In addition to the interactions of the endothelium with blood coagulation factors, endothelial cells also express cell-surface molecules that orchestrate the trafficking of circulating blood cells. These cell-associated molecules help direct the migration of leukocytes into specific organs under physiologic conditions and accelerate migration toward sites of inflammation. They have also been implicated in the adhesion of platelets and erythrocytes in several common disorders associated with homeostasis.

Interactions of Leukocytes With the Vessel Wall

It is now well established that flowing leukocytes may adhere to specific regions of the endothelium in response to tissue injury or infection. These multicellular interactions are essential precursors of physiologic inflammation. Leukocytes interact with vessel surfaces through a multistep process that includes (1) initial formation of usually reversible attachments; (2) activation of the attached cells; (3) development of stronger, shear-resistant adhesion; and (4) spreading, emigration, and other sequelae[36] (Fig. 27.4).

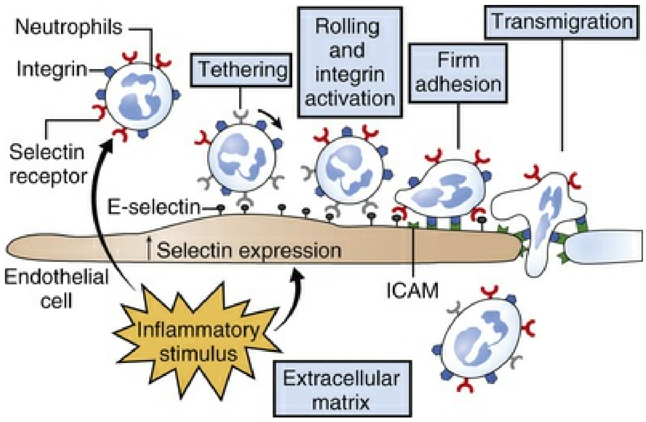

FIG. 27.4 Leukocyte recruitment process and transmigration. The multistep model for leukocyte recruitment at sites of inflammation begins with the activation of neutrophils and endothelial cells. Once activated, endothelial cells express selectins, whose binding to neutrophils initiates rolling and adhesion of neutrophils to the endothelium. Activated integrins on the surface of neutrophils bind to endothelial cell ICAMs, facilitating a firm adhesion. Transmigration through the endothelium further involves interactions with other molecules such as PECAMs and cadherins on the surface of endothelial cells.

Selectins are key molecules in the interaction of leukocytes and endothelial cells. They are transmembrane glycoproteins that recognize cell-surface carbohydrate ligands found on leukocytes and initiate and mediate tethering and rolling of leukocytes on the endothelial cell surface. Selectins constitute a family of three known molecules. L-selectin is expressed on most leukocytes and binds to ligands constitutively expressed on endothelial cells found in venules of lymphoid tissues. Its expression is induced on endothelium at sites of inflammation. E-selectin is expressed on activated endothelial cells and leukocytes. P-selectin is rapidly redistributed from secretory granules to the surface of platelets and endothelial cells stimulated with thrombin. Both endothelial cell E-selectin and P-selectin bind to ligands on leukocytes.[37]

With stimulation, leukocytes usually attach to postcapillary venule endothelial cells, where shear stresses are lowest. Leukocytes adherent to the endothelium can make contact with flowing leukocytes through the L-selectin molecule, resulting in amplification of leukocyte recruitment to sites of inflammation. It is generally understood that selectins initiate inflammatory, immune, and hemostatic responses by promoting transient multicellular interactions.[41]

Proinflammatory molecules presented on the surface of the endothelium proceed to activate a second family of adhesion molecules, the integrins, and cause cells to firmly adhere. After the initial tethering of leukocytes to endothelial cells, leukocytes then must roll prior to transmigrating through the endothelium. Inhibition of leukocyte adhesion does not reduce leukocyte rolling, suggesting that rolling and adhesion are distinct molecular events. In addition, inhibiting rolling reduces adhesion, suggesting that rolling is a prerequisite of leukocyte adhesion/recruitment and ultimately the inflammatory response.

Leukocytes subsequently migrate between endothelial cells into tissues by mechanisms that are not completely understood but that we know are affected by gradients of chemokines, integrins activation states, and interactions with PECAM-1,

an Ig-like receptor. This migration requires disruption of endothelial-cell-to-endothelial-cell interaction of cadherins at tight junctions. Leukocyte recruitment to lymphoid tissues or inflammatory sites requires the coordinated expression of specific combinations of adhesion and signaling molecules. Diversity at each step of the cascade ensures that the appropriate leukocytes accumulate for a restricted period in response to a specific challenge.[4,41]

Platelet Adhesion

Endothelial cells and circulating platelets normally do not interact with each other due to the release of PGI_2, the release of NO, and the expression of CD39 on the surface of endothelial cells.[42] During vascular injury and inflammation, platelets adhere to exposed subendothelial components and are rapidly activated. Circulating platelets interact with the adherent platelets, producing a hemostatic plug that promotes thrombin generation and development of a stable fibrin clot. High shear stress, as seen in arteries, increases platelet adherence to the subendothelium where unactivated platelets attach to the subendothelium through interactions of platelet glycoproteins with immobilized von Willebrand Factor (vWF), a large, multimeric protein with binding sites for several other molecules, including subendothelial collagen. Flowing platelets attach transiently to vWF, resulting in continuous movement of the cells along the surface. Under the lower shear stresses found in veins, unactivated platelets interact with integrins to attach to and immediately arrest on immobilized fibrinogen.[43]

Once platelets adhere to either vWF or fibrinogen, they are activated by secreted products such as adenosine diphosphate or epinephrine or by surface molecules such as collagen that cross-link the integrins and other platelet receptors. The activated platelets spread and adhere more avidly to the subendothelial surface, which recruits additional platelets into aggregates. Shear-resistant adhesion may be further enhanced by interactions of other integrins or receptors with laminin, fibronectin, and thrombospondin. As thrombin is generated, converting bound fibrinogen to fibrin, the aggregated platelets contract to strengthen the clot.[43]

Endothelial Permeability

Transport across the endothelium can occur via two different pathways: through the endothelial cell (transcellular) or between adjacent cells (paracellular), through interendothelial junctions (Fig. 27.5). The endothelial cell is able to dynamically regulate its paracellular and transcellular pathways for transport of plasma proteins, solutes, and liquid. The semipermeable characteristic of the endothelium (which distinguishes it from the epithelium) is crucial for establishing the transendothelial protein gradient (the colloid osmotic gradient) required for tissue fluid homeostasis. The transcellular pathway, also known as transcytosis, is defined as vesicle-mediated transport of macromolecules, such as plasma proteins, across the endothelial barrier in a caveolae-dependent manner. The paracellular pathway is formed by the minute intercellular space between contacting cells. Its primary function is to restrict free passage of macromolecules in the range of 3 nm and above through interendothelial junctions (IEJs), while allowing the convective and diffusive transport of molecules of less than 3 nm in diameter. Permeability of the IEJs is determined by the adhesive properties of the proteins that comprise the tight

junctions and adherens junctions. However, the junctional barrier is a dynamic structure. It responds to permeability-increasing agonists and migrating leukocytes with disassembly of IEJs and to barrier-stabilizing mediators by increasing the surface expression and adhesiveness of junctional proteins in order to strengthen IEJs.[44-46]

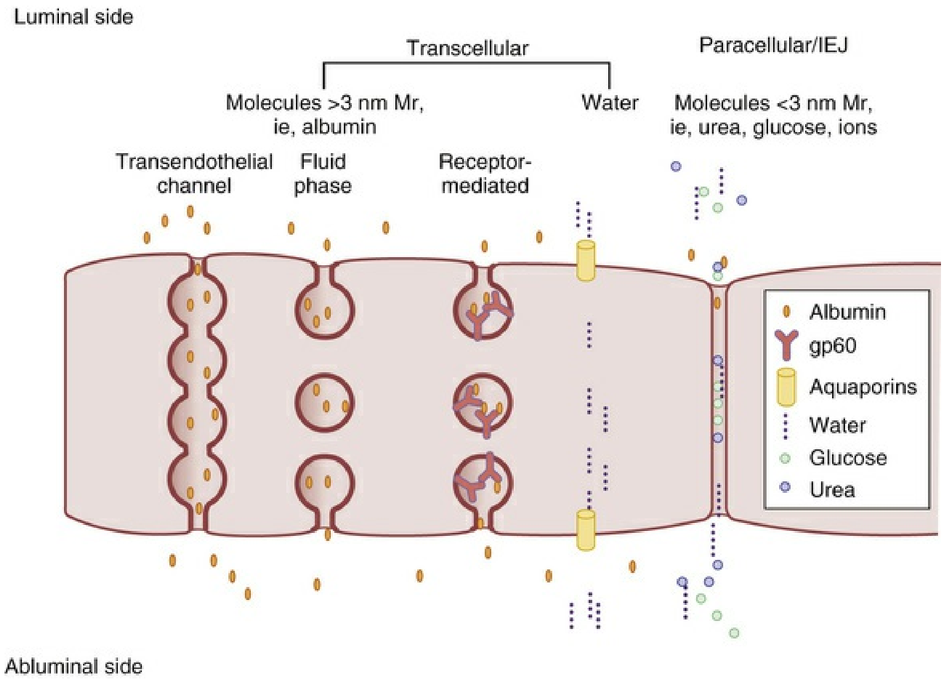

FIG. 27.5 Schematic of transport pathways in continuous endothelium. Under basal conditions, the transcellular pathway can mediate the transport of plasma proteins (>3 nm Mr) such as albumin by caveolae via an absorptive (receptor-mediated) or fluid-phase pathway. Transcellular channels can also form transiently in endothelial cells by fusion of multiple caveolae and allow albumin transport. Aquaporins form channels across the lipid bilayer that are highly selective for water molecules and allow their movement across the luminal or abluminal endothelial membrane, thus creating a transendothelial pathway for water. Small molecules including urea and glucose (<3 nm Mr) are transported around individual endothelial cells via the paracellular (ie, interendothelial junction [IEJ] pathway). *Mr*, molecular radius. (Modified from Mehta D, Malik AB. Signaling mechanisms regulating endothelial permeability. Physiol Rev. 2006;86:279-367.)

Endothelial Cell Dysfunction

Ischemia-Reperfusion Injury

Reperfusion of previously ischemic tissues can place the organs at risk for further cellular injury, thereby limiting the recovery of function. The microvasculature, particularly the endothelial cells, is vulnerable to the deleterious consequences of ischemia and reperfusion (I/R). I/R is now recognized as a potentially serious problem encountered during a variety of standard medical and surgical procedures, such as thrombolytic therapy, organ transplantation, and cardiopulmonary bypass.[47]

Hypoxia and inflammation are intimately linked on many levels and have functional roles in many human diseases. Indeed, a wide range of clinical conditions are characterized by hypoxia- or ischemia-driven inflammation or by inflammation-associated hypoxia. The molecular and biochemical changes in the vascular wall during I/R are characteristic of an acute inflammatory response (Fig. 27.6). The intensity of this inflammatory response can be so severe that the injury response to reperfusion is also manifested in susceptible organs such as in the lungs and cardiovascular system. The resulting systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS) are both associated with significant increases in mortality and morbidity.[48]

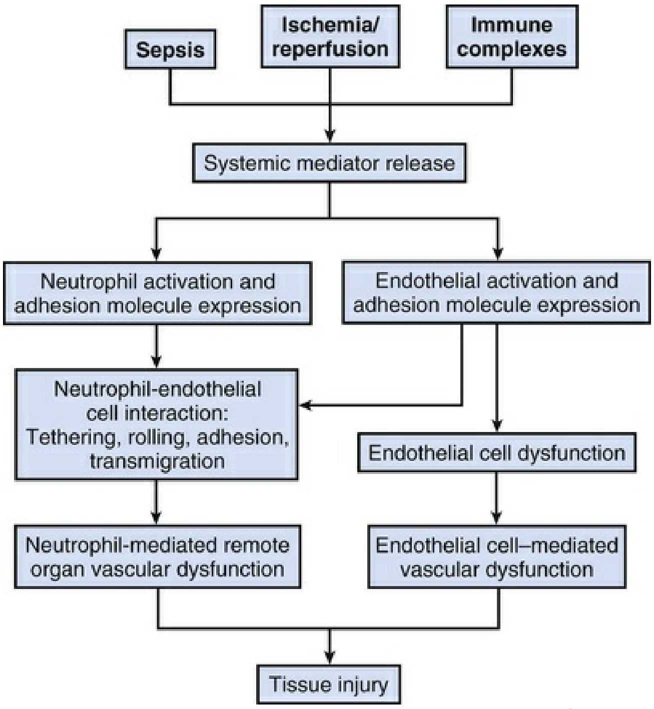

FIG. 27.6 Mechanisms that underlie the development of local and remote organ injury following an initial inflammatory event. The activation of endothelial cells and circulating neutrophils leads to the expression and activation of adhesion molecules that facilitate neutrophil invasion of vascular beds, resulting in local and remote organ dysfunction.

Microvascular dysfunction associated with I/R is manifested as impaired endothelium-dependent dilation in arterioles, enhanced fluid filtration, leukocyte plugging in capillaries, and the trafficking of leukocytes and plasma protein extravasation in postcapillary venules. During the initial period following reperfusion, activated endothelial cells in the microcirculation produce more oxygen radicals and less nitric oxide. The resulting imbalance between superoxide and nitric oxide in endothelial cells leads to the production and release of inflammatory mediators (eg, platelet-activating factor, TNF-α) and enhances the biosynthesis of adhesion molecules that mediate leukocyte-endothelial cell adhesion.[48]

Since its discovery in the early 1990s, hypoxia-inducible factor 1 (HIF-1) has been increasingly recognized for its key role in transcriptional control of more than a hundred genes that regulate a wide spectrum of cellular functional events, including

angiogenesis, vasomotor control, glucose and energy metabolism, erythropoiesis, iron homeostasis, pH regulation, cell proliferation, and viability. Animal studies have provided compelling data to demonstrate a pivotal role for the HIF pathway in the pathogenesis of ischemic injury. For example, HIF-1α has been shown to play a role in mediating cardioprotection.[49]

The inflammatory mediators released as a consequence of reperfusion also appear to activate endothelial cells in remote organs that are not exposed to the initial ischemic insult. Oxidants and activated leukocytes have been implicated as mediators of remote organ injury in I/R. This distant response to I/R can result in leukocyte-dependent microvascular injury that is characteristic of SIRS and MODS. The pulmonary damage associated with MODS can range from mild dysfunction to severe failure, as in acute respiratory distress syndrome (ARDS). The pulmonary injuries associated with ARDS include increased pulmonary microvascular permeability and the accumulation of neutrophil-rich alveolar fluid. Respiratory failure often is associated with cardiovascular, hepatic, gastrointestinal, and renal dysfunction as well as central nervous system involvement. MODS is associated with dysfunction of the coagulation cascade and the immune system, resulting in thrombosis, disseminated intravascular coagulation, and immunocompromise. The initiation of MODS may also lead to further tissue ischemia, resulting in additional insult.[50]

Sepsis

Although the pathophysiologic process of multiple organ dysfunction during sepsis is multifactorial, one common feature is the dysfunction of the microcirculation, including the resistance arteries, capillaries, and postcapillary venules. The microcirculation cannot be considered a simple passive conduit. Rather it is a functionally active system of interactions among the vascular wall; circulating and tissue-associated cells such as leukocytes, platelets, and mast cells; and extracellular mediators that contribute to the regulation of local, downstream, and upstream vascular tone. Sepsis is particularly associated with microvascular endothelial cell dysfunction leading to (1) the breakdown of endothelial barrier function, leading to tissue edema and uncontrolled inflammatory cell infiltration; (2) vasomotor dysfunction, leading to the formation of arteriovenous shunts in association with loss of peripheral resistance; and (3) disturbance of oxygen transport and utilization by tissue cells.[51]

Another major mechanism during sepsis is the change from anticoagulant to procoagulant and the contribution of microthrombi to the disturbance of the microcirculation. Lipopolysaccharide (LPS), an important pathogen product, is recognized by pathogen recognition receptors like toll-like receptors on cells of the innate immune system. This will lead to intracellular signaling and to the production of cytokines and other potent chemokines.

Septic shock is often associated with the loss of fluid from the intravascular into the extravascular space with the potential progressive loss of circulating blood, eventually leading to a depression of cardiac output. Similarly, loss of fluid into the extravascular space can lead to life-threatening edema in the lungs, kidney, and brain of septic patients. The loss of fluid is not believed to be associated with changes in hydrostatic or osmotic pressures within the vascular compartment but

rather to the breakdown of endothelial barrier function. The permeability of the vascular barrier can be modified in response to specific stimuli acting on endothelial cells. Many inflammatory agonists mediate endothelial hyperpermeability via a calcium-dependent mechanism. Multiple cascades of intracellular signaling reactions are initiated when an inflammatory agonist binds to its respective receptor expressed on the endothelial surface (eg, thrombin binds the protease-activated receptor-1, histamine binds its receptor H1, and vascular endothelial growth factor binds its receptor vascular endothelial growth factor 2 (VEGFR-2). This breakdown allows migration of water and macromolecules, including proteins, into the extravascular space. The pathophysiologic mechanisms proposed include the separation of tight junctions between endothelial cells, as well as cytoskeleton contraction, rather than destructive changes of endothelial cells leading to defects in the endothelium.[44,52] Studies on the microcirculation of the gut have shown the development of a gap between microvascular and venous oxygen tension, suggesting enhanced shunting of the microcirculation. Defects in distributing blood to regional vascular beds or the microcirculation could be responsible for tissue hypoxia and limited oxygen extraction. Clinical evidence of decreased microvessel density in the sublingual microcirculation of fluid-resuscitated septic patients is consistent with findings of decreased functional capillary flow in the gut, liver, and skeletal muscle microcirculation in animal models of sepsis. This clinical finding raises the possibility that abnormal microvascular O_2 transport develops in multiple organs despite fluid resuscitation, leading to heterogeneous microvascular dysfunction and local tissue hypoxia in severe cases of sepsis.

Hemolytic-Uremic Syndrome

Thrombotic thrombocytopenic purpura (TTP) and the hemolytic-uremic syndrome (HUS) are related disorders characterized clinically by microangiopathic hemolytic anemia and thrombocytopenia. Pathologically, both conditions include the development of platelet microthrombi that occlude small arterioles and capillaries. Endothelial dysfunction plays a prominent role in the pathogenesis of both disorders. HUS commonly occurs in early childhood (approximately 90% of cases). It often follows an episode of bloody diarrhea caused by enteropathic strains of *Escherichia coli* that release an exotoxin, verotoxin-1 (VT-1) (see also Chapter 75). VT-1 binds with high affinity to receptors expressed in high density on renal glomerular endothelial cells. VT-1 is directly cytotoxic to endothelial cells where it promotes neutrophil-mediated endothelial cell injury. VT-1 induces the production of TNF-α by monocytes and cells within the kidney. In turn, TNF-α, in synergy with interleukin-1, increases VT-1 receptor expression and exacerbates the sensitivity of the endothelium to toxin-mediated and antibody-mediated cytotoxicity. It also promotes vWF release and impairs fibrinolytic activity.[53]

There is considerable evidence to suggest that endothelial cell injury plays a role in the pathogenesis of TTP. Platelet microthrombi in TTP contain abundant vWF but little fibrinogen, in contrast to those seen in disseminated intravascular coagulopathy. A subgroup of patients has been identified who suffer from chronic, relapsing TTP and whose plasma continues to contain elevated levels of unusually large vWF multimers (ULvWF) between relapses. ULvWFs may exacerbate microvascular thrombosis through their ability to aggregate platelets at high levels

of shear stress. The secretion of ULvWF by cultured endothelial cells is stimulated by many agonists, including Shiga toxin. However, elevated levels of vWF occur in other thrombotic microangiopathies, and their exact role in TTP/HUS requires further study. Endothelial damage plays a pivotal role in the pathogenesis of the disease. The events that initiate TTP remain unknown. More recently, plasma from patients with TTP and HUS has been reported to induce apoptosis in microvascular endothelial cells. Interestingly, cells from dermal, renal, and cerebral origin were most susceptible, whereas pulmonary and coronary arterial cells were less susceptible.[54]

Vasculitic Disorders

Vasculitis is a disease that targets all levels of the arterial tree from aorta to capillaries and also affects venules, with leukocyte infiltration and necrosis. Different forms of vasculitis attack different vessels and are classified accordingly. The inflammatory process may target vessels of any type throughout the vascular system, although distinct clinicopathologic entities preferentially involve vessels of particular sizes and locations. Small vessels anywhere in the body may be affected by focal necrotizing lesions where extravasation of leukocytes drives the inflammatory responses, resulting in vasculitis. Leukocyte adhesion molecules participating in the interactions with endothelial cells belong to three major families: selectins, sialomucins, and integrins. Interestingly, it is recognized that these interactions participate in tissue specificity in various vasculitic conditions. For instance, specific selectin interactions mediate cutaneous tropism in several inflammatory disorders, including graft-versus-host disease and dermatomyositis.[55]

Biomarkers of Endothelial Activation

There is a strong rationale for targeting markers of endothelial cell activation as clinically informative biomarkers to improve diagnosis, prognostic evaluation, or risk-stratification of critically ill patients. During sepsis, a large number of endothelial cell-active molecules are potential biomarkers for the early diagnosis. These include regulators of endothelial activation, such as vascular endothelial growth factor (VEGF), the angiopoietin pathway (Ang-1/2), adhesion molecules (ICAM, VCAM, and E-selectin), mediators of permeability and vasomotor tone (ET-1), and mediators of coagulation (eg, vWF).[56] Elevated endothelin levels have been found in systemic and pulmonary hypertension, coronary artery disease, and heart failure, although the role of ET-1 in the pathophysiology of these conditions has been postulated but not proved.[57,58]

Cellular markers such as EPC and endothelial microparticles (EMP) are also gaining interest as biomarkers. There is a positive correlation between EPC number and survival in sepsis.[59] In addition, there is a functional impairment of EPC with decreased proliferative and migratory capacities of EPC. These findings have led to therapeutic strategies (eg, statins) that focus on improving EPC number and function during sepsis.[60] In contrast, an elevation of EMP is considered a marker of endothelial dysfunction in cardiovascular disease. However, the number of EMP is positively related to survival and inversely correlated with the Sequential Organ Failure Assessment (SOFA) score in patients with sepsis. Because it is becoming

increasingly clear that microparticles are more than simple markers of endothelial damage or activation, their interpretation as markers of endothelial dysfunction is less ambiguous.[61] Interestingly, EPCs show a biphasic response after traumatic brain injury; after an initial decrease, they peak 7 days after the insult. Furthermore they have been associated with an improved outcome after traumatic brain injury.[62]

However, the clinical utility of these biomarkers is limited by a lack of assay standardization, unknown receiver operating characteristics, and lack of validation. It remains speculative whether the use of endothelial cell biomarkers will guide therapy during critical care illness in the near future.

Conclusions

The endothelium can no longer be viewed as a static physical barrier that simply separates the blood from tissue. Rather, the endothelium coordinates key functions of different tissues in normal and pathophysiologic conditions. This is accomplished by the interaction of endothelial cells with circulating factors and cells and its ability to transmit biochemical and biophysical signals to surrounding tissues. A greater understanding of endothelial physiology will lead to novel therapeutic approaches in complex clinical conditions.

CHAPTER 28

Principles of Invasive Monitoring

Molly V. Dorfman, Kenneth A. Schenkman

PEARLS

- Hemodynamic monitoring refers to measurement of the functional characteristics of the heart and circulatory system that affect the perfusion of tissues with oxygenated blood.
- Hemodynamic monitoring can be performed invasively or noninvasively and can be used for diagnosis, surveillance, or titration of therapy.
- The central venous waveform is composed of three waves (*a*, *c*, and *v*) and two wave descents (*x* and *y*).
- The arterial waveform has three components: rapid upstroke, dicrotic notch, and runoff.
- Cardiac output can be calculated using the Fick method or measured directly via thermodilution.
- Continuous SvO_2 monitors can guide goal-directed therapy in patients who are in septic shock.
- A pulmonary artery catheter can be used to measure cardiac output and indices of oxygen delivery and extraction.
- Newer minimally invasive modalities complement historically invasive devices for assessing hemodynamics.

Role of Invasive Hemodynamic Monitoring

Since William Harvey's observation in the early 1600s that the heart pumps blood in a continuous circuit, the function of the circulatory system has been the subject of intense scrutiny. Hemodynamic monitoring refers to measurement of the functional characteristics of the heart and the circulatory system that affect the perfusion of tissues with oxygenated blood in order to maintain homeostasis and to remove byproducts of metabolism. Several different types of invasive hemodynamic monitoring can be used concurrently to guide management. The goal of hemodynamic monitoring is to provide accurate diagnoses and to guide additional

interventions to deliver improved care to the critically ill patient.

In his 1733 report "Statical essays: containing haemastaticks; or, an account of some hydraulick and hydrostatical experiments made on the blood and blood-vessels of animals," Hales[1] described early experiments in horses in which he used tubular devices inserted directly into arteries to measure intravascular pressures. Fig. 28.1 depicts Hales and an assistant in the process of these early experiments. This figure also illustrates a simple method for inferring arterial versus venous placement of a vascular catheter, which can also give a quick bedside estimate of central venous pressure.

FIG. 28.1 Clinician and an assistant measuring the blood pressure of a horse. (From Pickering G. Systemic arterial hypertension. In: Fishman AP, Dickinson WR, eds. Circulation of the Blood: Men and Ideas. New York: Oxford University Press; 1964.)

Clinical hemodynamic assessment at the bedside begins with noninvasive measurements such as heart rate (HR), blood pressure, urine output, and peripheral perfusion. Other noninvasive studies that may contribute to assessment of hemodynamic status include electrocardiograms, chest radiographs, ultrasound, and echocardiography. Frequently, in the pediatric intensive care unit (PICU) these measurements are supplemented by invasive hemodynamic measures that require entrance into the intravascular space. Such invasive hemodynamic measurements include placement of central venous catheters to assess right atrial filling pressures

and to measure mixed venous oxygen saturation, arterial catheters to assess arterial blood pressure, and pulmonary artery catheters (PACs) to assess left-sided pressures, cardiac output (CO), and vascular resistance. Although invasive hemodynamic monitoring can provide the skilled intensivist with a plethora of valuable information, it is not meant to take the place of, or minimize, the extensive amount of information that can be gained by less invasive techniques. Successful use of invasive hemodynamic measurements necessitates skills to obtain these measures safely with utmost attention to the multiple potential risks imposed upon the patient. Furthermore, for invasive hemodynamic measurements to be useful, the clinician must be able to successfully interpret the information provided by the measurements. Finally, as with any technology, the use of invasive hemodynamic monitoring is in evolution, and it is incumbent upon the clinician to be familiar with developments as they arise.

This chapter aims to be a practical guide to the use of hemodynamic monitoring in the PICU. The chapter reviews general principles of measurement and then discusses the three main types of invasive hemodynamic monitoring: central venous catheter, arterial catheter, and PAC. It addresses the indications and controversies, sites of insertion, interpretation of waveforms, and potential complications. It also reviews CO monitoring and calculation of oxygen consumption and delivery. New techniques coupling invasive monitoring with noninvasive devices are also discussed. Chapter 19 details the specific techniques for gaining access in order to make these measurements.

Indications for Invasive Hemodynamic Measurements

The three main indications for invasive hemodynamic monitoring are diagnosis, surveillance, and titration of therapy. Diagnosis may include the differentiation of septic shock (through assessment of factors such as diminished right heart filling pressures or preload and decreased systemic vascular resistance) from cardiogenic shock (characterized by elevated left heart pressures and afterload). Surveillance implies observation over time. The purpose of surveillance may be to assess the stability of a patient at risk for adverse changes or to determine the response to therapy. Invasive measurements performed for diagnostic purposes often are continued for surveillance. Titration of therapy is often based on information gleaned from invasive measurements.

Principles of Measurement

Intensive care clinicians rely on a wide variety of measurement systems to assess patient clinical status and response to therapy. However, not all clinicians have a good understanding of how physiologic variables are measured and, consequently, may not be able to troubleshoot monitoring systems or recognize when information obtained is inaccurate. A detailed discussion of monitoring is beyond the scope of this chapter, but a basic understanding of the principles of measurement is helpful in deciding which measurements to trust and how to assess a monitoring system for accuracy. Detailed descriptions of monitoring systems are provided elsewhere.[2-4]

Signal Analysis

Measurements generally are made directly by comparison with known standards or indirectly by use of a calibration system. Determination of length or weight usually is made by direct comparison with a standard ruler or standard mass. Most invasive measurements in the ICU are made indirectly, therefore requiring use of a calibration system. Thus understanding the basis for calibration of a system is important to determine the validity of the measurement.

Measurement systems detect and transform signals so that they can be presented in an interpretable way to the user. Signals can be characterized as static or dynamic. Slowly changing signals, such as body temperature, can be thought of as static. Hemodynamic measurements change from moment to moment and thus are dynamic. Physiologic signals may be periodic; for example, arterial pressure is periodic because it varies with the cardiac cycle.

Complex periodic signals, such as an arterial pressure waveform, can be described mathematically as the sum of a series of simpler waveforms called a Fourier series. Alternatively, the arterial tracing can be thought of as a sum of simpler waveforms, sine waves, and cosine waves. Fig. 28.2 depicts an arterial pressure waveform as the sum of the first six terms in the Fourier series. The sum of the first six terms in the series forms a waveform similar to the original tracing. Adding terms from the Fourier series, or higher harmonics, results in an increasingly better representation of the actual waveform. In general, to reproduce a pressure tracing without loss of significant characteristics for clinical use, the measurement system must have an accurate frequency response to approximately 10 times the fundamental frequency (first 10 harmonics).

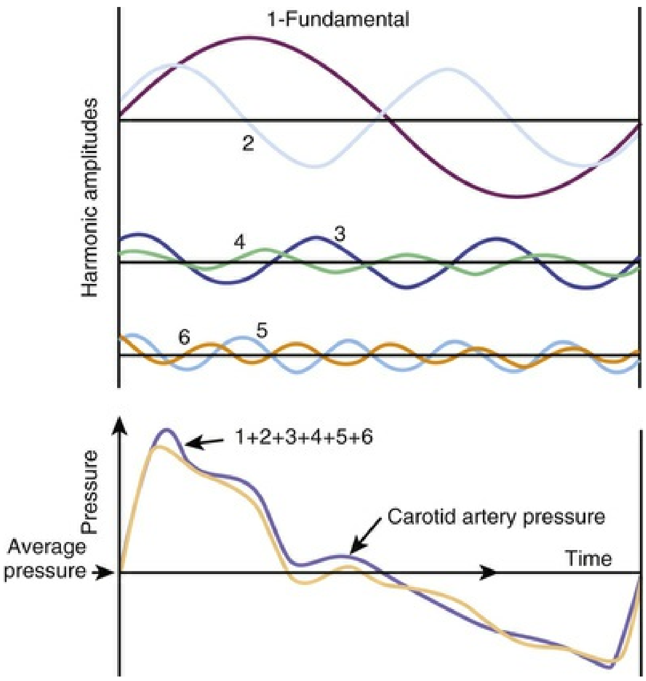

FIG. 28.2 Fourier series representation of an arterial pressure tracing. Bottom, High-fidelity carotid artery pressure tracing and the sum of the first six harmonics of its Fourier series representation. Despite the few terms used in the synthesis, the close fit of the two curves is evident. Top,

Individual harmonic components labeled with their harmonic number. (Redrawn from RSC. Transducers for Biomedical Measurements: Principles and Applications. New York: John Wiley & Sons; 1974, from Hansen AT. Acta Physiol Scand. 1949;19[suppl 68]:1 and Perloff WH: Invasive measurements in the PICU. In: Fuhrman BP, Zimmerman JJ, eds. Pediatric Critical Care. 2nd ed. St. Louis: Mosby; 1998.)

The sampling rate of a measurement system determines how often a physiologic value is measured. For body temperature, sampling every few minutes might be sufficient, but for arterial pressure measurement, a higher rate is necessary. This principle may seem obvious, but as an example of the importance of sampling rate, consider the number of points needed to define a circle. If we place three equidistant points on a circle, we describe a triangle, not a circle. Similarly, four points describe a square. If we increase the number of points (sampling rate), we describe the circle more completely. For a sine wave, the minimum frequency of sampling needed to preserve the waveform is twice the frequency. This mathematical minimum is known as the Nyquist frequency.[4] For complex waveforms such as arterial pressure tracings, the sampling rate must be at least twice the highest frequency component in the waveform.

Measurement Systems

Hemodynamic monitoring in the clinical setting usually uses a fluid-coupled system where changes in pressure are transmitted via a column of (incompressible) fluid in a (ideally incompressible) tube to a mechanical transducer. The mechanical transducer, usually a displaceable screen diaphragm, converts a change in pressure to an electrical signal, which can be processed and displayed. In laboratory settings, vascular pressures can be measured by a transducer at the point of interest rather than remotely, as in the clinical setting. Measuring pressure at the point of interest—directly in the aorta, for example—decreases loss of signal integrity because of the measurement system. Most clinical pressure measuring systems have sufficient fidelity for clinical purposes. However, compliance, resistance, or impedance in the pressure tubing can result in damping or alteration of the recorded signal. The presence of bubbles in the fluid can further damp the recorded signal.

Errors in Measurement

The ideal measurement system determines the actual or "true" value for the measured variable. However, determination of a true value may be difficult. Every measurement system is subject to various errors. Errors in measurement can be classified as either systematic or random. Systematic errors occur in a predictable manner and are reproduced with repeated measures. Bias in a measurement system—for example, a baseline offset—results in a systematic error. Random errors are unpredictable and do not recur predictably with repeated measures.

Accuracy of a measurement is defined by the difference between the measured and true values, divided by the true value. Precision is defined by the reproducibility of the measurement; thus a more precise system yields more similar values for repeated measures under the same conditions than does a less precise system. Imprecision can be thought of as a representation of random errors, whereas bias can be thought of as a representation of systematic errors.

Calibration

Many measurement systems are linear, that is, based on an assumption that the relationship between the inputs and outputs from a measurement device can be fitted to a straight line. This assumption allows a system to be calibrated under two conditions, with the rest of the values falling on the line defined by those two points. Actual nonlinearity of the system adversely affects the measurements.

Calibration is a process in which the reading, or output of a device, is adjusted to match a known input value. For example, an electronic pressure transducer may be calibrated against a mercury manometer. If the input to the device is zero, the output should be adjusted so that the reading also is set to zero. This "zeroing" reduces any baseline offset, thus reducing systematic errors in subsequent readings. The system then is calibrated to a nonzero value, for example, 100 mm Hg pressure, and the system gain is adjusted to read this value as well.

Frequency Response

The ability of a measurement system to accurately measure an oscillating signal, such as arterial blood pressure, is dependent upon the system's frequency response. The system can either overestimate or underestimate the true amplitude of a signal. If the system is overdamped, the value reported underestimates the amplitude, and waveform characteristics may be lost. Resonance in the system may result in overestimation of the amplitude. Measurement of arterial systolic pressure—the amplitude of the arterial waveform—may be inaccurate because of overdamping, and important waveform characteristics may be lost if the frequency response of the measurement system is poor. Fig. 28.3 illustrates the effects of damping on measurement of blood pressure.

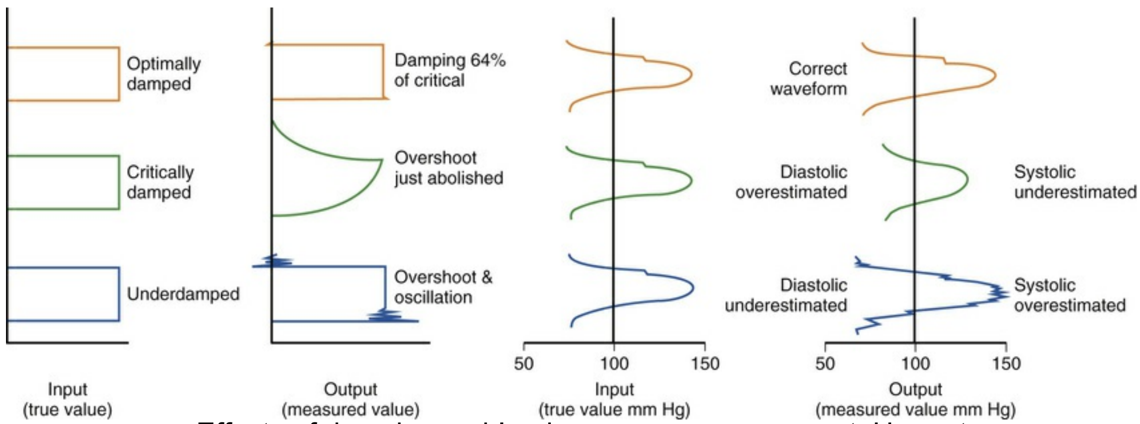

FIG. 28.3 Effects of damping on blood pressure measurement. Upper two graphs depict the response to a square-wave input from three different blood pressure transducers with different damping. Lower two graphs show the effect of damping on blood pressure measurement. (From Chatburn RL. Principles of measurement. In: Tobin MJ, ed. Principles and Practice of Intensive Care Monitoring. New York: McGraw-Hill; 1998.)

Impedance

Impedance is the ratio of the change in blood flow along a vessel to the change in the pressure in the vessel. Impedance has both resistive and reactive components. In a pulsatile system such as the cardiovascular system, resistance alone does not fully describe the impediment or impedance to forward flow of blood. The caliber, length, and arrangement of the blood vessels and the mechanical properties of the blood determine resistance in the blood vessels. Reactance includes compliance of the vessels and inertia of the blood and thus is a dynamic component of impedance. This is important because the pulsatile nature of the cardiovascular system is dynamic.

When blood is propelled through a vessel at a branch point, a reflected pressure wave back toward the heart increases the impedance of the system. The major sites of wave reflection from vessel branching are from vessels approximately 1 mm in diameter.[2] Thus these small vessels contribute significantly to overall impedance. Fig. 28.4 shows the relationships between pressure and flow velocity with distance along the length of the aorta. Because blood pressure increases with distance from the heart and flow velocity decreases with distance, the impedance increases toward the peripheral vasculature. Hemodynamic measuring systems are essentially physical extensions of the vascular system; thus the configuration and characteristics of the tubing and transducer system can alter the overall effect of impedance.

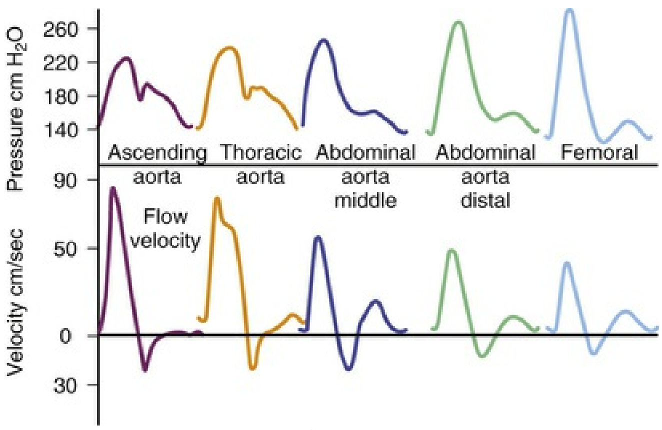

FIG. 28.4 Pressure pulses and flow velocity at various points in the systemic arterial circulation. Data were obtained from dogs and are similar to measurements made in humans. The data indicate that both peak and pulse pressure increase with distance from the heart, whereas oscillation in flow velocity shows a progressive decrease. Consequently impedance (discussed in the text) must increase toward the periphery. (From Perloff WH. Invasive measurements in the PICU. In: Fuhrman BP, Zimmerman JJ, eds. Pediatric Critical Care. 2nd ed. St. Louis: Mosby; 1998.)

Invasive Techniques

Central Venous Pressure Catheters

Indications

Indications for CVP catheter placement in pediatric patients include assessment of right heart filling pressure (CVP), monitoring of large fluid shifts between the

intravascular and the extravascular space, infusion of vasoactive substances, monitoring mixed venous oxygen saturation, and infusion of hyperosmolar fluids and/or irritants.[5-7]

Interpretation of Waveforms

CVP is a measure of right atrial pressure, although it may be measured in the inferior or superior vena cava (SVC). It is a measure of preload—the force or load on the right ventricle during relaxation or filling. CVP is measured at the end of diastole, just prior to ejection. Final filling of the right ventricle occurs at the end of atrial contraction. When the tricuspid valve is open during diastole, the right atrium and right ventricle form a continuous column; therefore right atrial pressure reflects right ventricular end-diastolic pressure. CVP is used to measure filling pressure or preload and is an indicator of volume status. It is commonly used in patients with hypovolemic or septic shock in whom volume resuscitation is desirable prior to institution of vasopressor therapy. In patients with decreased right ventricular function or pulmonary hypertension, an increased CVP well beyond normal limits may be observed and further fluid resuscitation may promote the development of congestive heart failure. Increases in the positive end-expiratory pressure can decrease preload despite a paradoxically increased CVP. Finally, increases in extrathoracic pressure, such as that caused by increased abdominal distension, can increase CVP.

The CVP waveform is divided into three components: *a, c,* and *v* waves (Fig. 28.5). Each component can be correlated with a specific portion of the electrocardiogram (ECG) tracing. The *a* wave occurs with atrial contraction and is seen after the P wave of the electrocardiogram during the PR interval. Thus the mean value of the *a* wave approximates right ventricular end-diastolic pressure. Cannon *a* waves (Fig. 28.6), which are enlarged *a* waves seen when the right atrium is ejecting against a closed tricuspid valve, may be seen when atrioventricular discordance occurs (ie, during junctional ectopic tachycardia, ventricular tachycardia, or heart block). The *c* wave occurs in early systole with closure of the tricuspid valve and is seen at the end of the QRS complex in the RST junction. The *v* wave occurs during filling of the right atrium in late systole before opening of the tricuspid valve and is seen between the T and P waves of the ECG. The *v* wave is increased in the setting of tricuspid regurgitation. The x descent is the decrease in pressure after the *a* wave, reflecting atrial relaxation. The y descent is the decrease in pressure that occurs after the *v* wave as the tricuspid valve opens and passive filling of the right ventricle occurs.

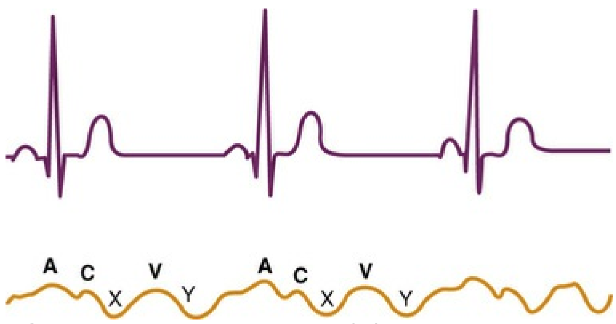

FIG. 28.5 Central venous pressure *(A)* tracing with corresponding electrocardiogram (ECG). The *a* wave is produced by atrial contraction

and occurs after the P wave of the ECG during the PR interval. The *c* wave *(C)* is produced by closure of the tricuspid valve and takes place early in systole at the end of the QRS complex in the RST junction. The *v* wave *(V)* is caused by rapid filling of the right atrium late in systole before opening of the tricuspid valve and is seen between the T and P waves of the ECG. The x descent *(X)* reflects the decrease in pressure in the right atrium after the *a* wave as the tricuspid valve is pulled away from the right atrium by the right ventricle as it contracts during systole. The y descent *(Y)* is the decrease in right atrial pressure that occurs after the *v* wave as the tricuspid valve opens and blood moves from the right atrium into the right ventricle.

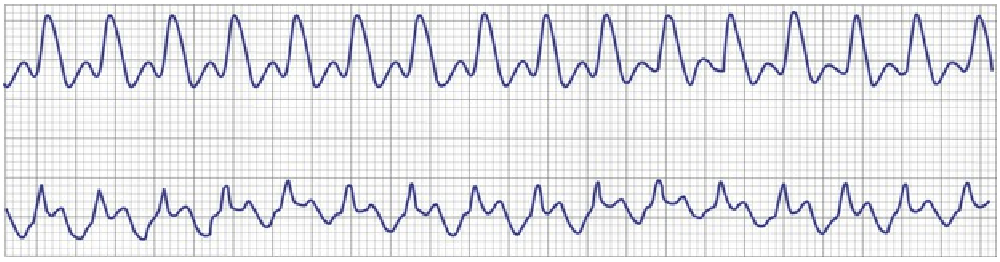

FIG. 28.6 Cannon *a* waves are enlarged *a* waves seen when the right atrium is ejecting against a closed tricuspid valve. These waves are typically seen when atrioventricular discordance occurs, such as during junctional ectopic or ventricular tachycardia or heart block.

Continuous Mixed Venous Oxygen Saturation

Mixed venous oxygen saturation (SvO_2) can be measured continuously by using a specially designed central venous catheter. These catheters have two to three lumens and have the same capabilities of standard central venous line catheters, with the additional potential for spectrophotometric monitoring. The SvO_2 catheters use reflection spectrophotometry and are able to read hemoglobin oxygen saturation continuously. The reflected light is dependent on the oxygenated and deoxygenated hemoglobin concentration in the circulating blood.[8]

SvO_2 is another parameter used to monitor the relationship between oxygen delivery and demand and is often used as a surrogate for cardiac index. Rivers et al.[9] showed that when continuous SvO_2 monitoring was used to guide resuscitation and hemodynamic support in patients with severe sepsis and septic shock, survival rates improved. Guidelines set forth by the American College of Critical Care Medicine/Pediatric Advanced Life Support have recommended goal-directed therapy with a target SvO_2 of ≥70% in children and adolescents who are in septic shock.[7] A randomized controlled trial conducted by Oliveira and colleagues[10] supported the use of these guidelines in children and adolescents with severe sepsis or fluid-refractory septic shock. Most recently, there has been lacking evidence[11-13] to support continuous SvO_2 monitoring for early goal-directed therapy in severe sepsis and septic shock, so the role of these catheters, in light of complication risks with invasive monitoring, is still evolving.

Ideally, the catheter should be placed in the right internal jugular vein, with the tip

taking measurements in the SVC. SvO_2 measurements obtained from the inferior vena cava exhibit greater variability because of fluctuations in splanchnic oxygen utilization and thus are less reliable. SvO_2 measurements from the right atrium contain coronary sinus blood and are more desaturated because of the high oxygen extraction rate of the myocardium. Studies in critically ill children have evaluated SvO_2 measurements obtained in the pulmonary artery and the SVC. Concordance analysis showed appropriate agreement in the measurements between these two sampling sites.[14] This finding has clinical importance because the use of PACs has declined, while central venous line use has increased.[15] Continuous SvO_2 monitoring can alert the intensivist to early changes in hemodynamic status, thus allowing for less frequent blood sampling through the central line and less risk of infection. Percutaneously placed SvO_2 central lines have even been used to monitor patients undergoing complex cardiac surgery, thus avoiding the risks associated with transthoracic lines following surgery.[16]

Arterial Pressure Catheters

Indications

The transition to direct monitoring of arterial blood pressure dates back to the mid-1950s when two separate studies compared invasive arterial measurements and noninvasive or cuff measurements in healthy adults.[17,18] Van Bergen and colleagues[18] noted a frequent difference between direct and indirect measurements, with indirect measurements increasingly lower than direct measurements as the systemic blood pressure increased. The greatest disparity was found in young hypertensive patients. Similarly, Cohn and Luria[19] observed that invasive arterial pressures were significantly greater than cuff pressures and emphasized the importance of direct measurements of systemic arterial pressure when caring for patients with hypotension and shock. Continuous direct monitoring of arterial blood pressure should be considered when treating patients who require more than minimal vasopressor therapy.

Indications for arterial catheterization include continuous monitoring of systemic arterial blood pressure, frequent blood sampling, and withdrawal of blood during exchange transfusions.[20] In addition to the value of the measurements themselves, these measurements provide components of derived measures of CO and oxygen delivery.

Interpretation of Waveforms

Systolic blood pressure (SBP) in children varies greatly with age and gender. As with the CVP waveform, the arterial waveform can be correlated with specific parts of the cardiac cycle. The arterial waveform has three main components (Fig. 28.7): (1) a rapid upstroke and downslope that correlates with systolic ejection, (2) a dicrotic notch that correlates with closure of the aortic valve, and (3) a smooth runoff that correlates with diastole. The dicrotic notch or incisura is decreased in situations of hyperdynamic CO in which left ventricular output and stroke volume (SV) are increased, pulse pressure is widened, and diastolic blood pressure (DBP) is increased (eg, surgical systemic-to-pulmonary shunts, patent ductus arteriosus, aortic regurgitation, anemia, fever, sepsis, hypovolemia, exercise). Conversely, cardiac

tamponade and severe aortic stenosis can narrow the pulse pressure and are associated with a deflection (anacrotic notch) on the ascending limb of the waveform.[21]

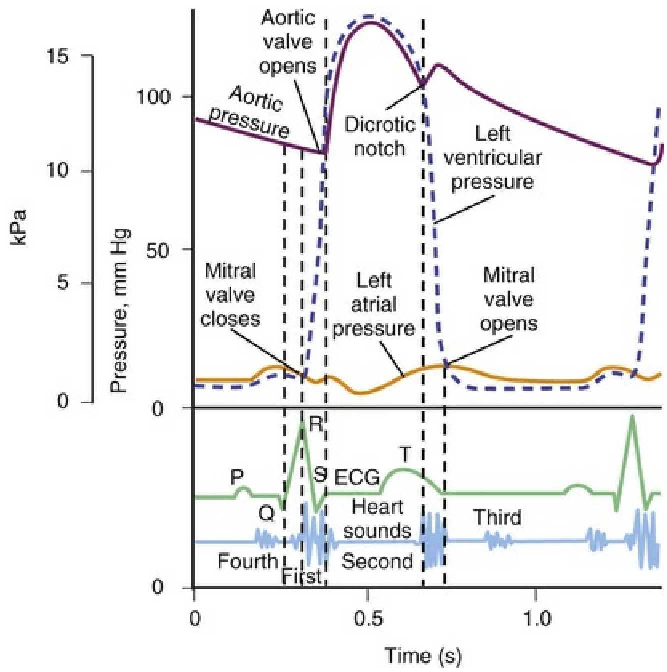

FIG. 28.7 Aortic, left ventricular, and left atrial pressure waveforms as they correspond to the electrocardiogram (ECG), opening and closing of the aortic and mitral valves, and heart sounds. Note the presence of the dicrotic notch on the descending limb of the aortic waveform. (From Peura RA. Blood pressure and sound. In: Webster JG, ed. Medical Instrumentation: Application and Design. Boston: Houghton Mifflin; 1978.)

Systolic pressures measured in the periphery typically are greater than those measured more centrally because of pulse amplification of pressure waves reflected back from arterial branch points[21,22] (see Fig. 28.4). More peripheral sites, such as the radial artery, have greater SBP and lower DBP than more central sites and thus taller and narrower waveforms with greater pulse pressures (difference between SBP and DBP). Important to note is that the mean arterial pressure (MAP in Eq. 28.1) represents the area under the waveform curve, and the overall magnitude of the reading remains the same regardless of the location of the tracing.

$$MAP = DBP + (SBP - DBP)/3 \qquad \textbf{Eq. 28.1}$$

The appearance of the arterial waveform also provides clinical information to the observer. Pulsus alternans (Fig. 28.8) is observed when regular variations occur in the amplitude of the peak systolic pressure during sinus rhythm. This phenomenon can be seen in patients with severe left ventricular failure. Pulsus paradoxus (Fig. 28.9) demonstrates an exaggerated decrease in the systolic pressure (>10 mm Hg) during the inspiratory phase of the respiratory cycle. This phenomenon can be observed in patients with pericarditis, pulmonary hyperinflation, and decreased

intravascular volume.

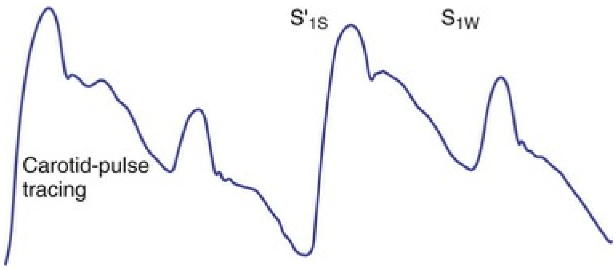

FIG. 28.8 Pulsus alternans occurs with left ventricular failure and is characterized by regular variations in the peak amplitude of systolic pressure during sinus rhythm. (Adapted from Cha K, Falk RH. Images in medicine: pulsus alternans. N Engl J Med. 1996;334:834.)

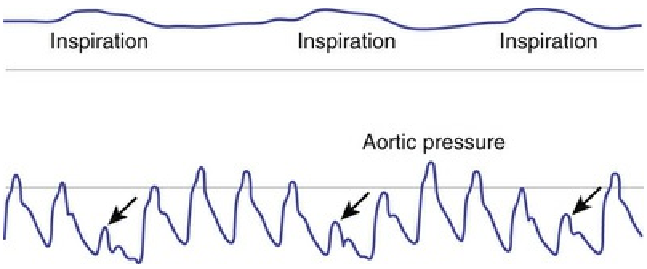

FIG. 28.9 Pulsus paradoxus is characterized by an exaggerated decrease in the systolic blood pressure during inhalation. It is commonly seen in conditions marked by great swings in intrathoracic pressure, such as in status asthmaticus, or when there are changes in cardiac function as in pericarditis. In severe hypovolemia, pulsus paradoxus also can be observed as a result of a decrease in preload. (Adapted from Wu LA, Nishimura RA. Images in clinical medicine: pulsus paradoxus. N Engl J Med. 2003;349:7.)

Pulmonary Artery Catheters

History and Controversy

In 1847, Claude Bernard described a method for measuring intracardiac pressures in animals by inserting a glass tube in the heart.[23] However, the true pioneers of cardiac catheterization were two other Frenchmen: Jean Baptiste Auguste Chaveau, at that time a veterinarian interested in the relationship between the dynamic motion of the heart and heart sounds, and Etienne-Jules Marey, a physician interested in the physiology of the circulation. In the early 1860s, using techniques adapted from Bernard's work, Chaveau and Marey inserted a double-lumen catheter into the right atrium of a horse to record phasic changes in intracardiac pressures as they simultaneously recorded the apical impulse.[23-26]

Right heart catheterization was not considered a safe practice in humans until the early 20th century. In 1929, Werner Forssman, a German surgeon, secretly performed a right heart catheterization on himself. In direct contradiction to his supervisor's instructions, Forssman inserted a urinary catheter into his own left

antecubital vein, and then the remainder of the way to his right atrium under fluoroscopic guidance with the aid of a mirror. Forssman performed right heart catheterizations on himself a total of nine additional times without adverse consequences and expanded his findings by demonstrating the feasibility of injecting contrast dye during the procedure.[27,28]

In the early 1940s, Andres Cournand and Dickinson Richards, working at Bellevue Hospital in New York City, continued Forssman's work. They performed right heart catheterization in healthy humans and in those with cardiac failure.[28-31] In 1956, Forssman, Cournand, and Richards won the Nobel Prize in Physiology or Medicine for their discoveries relating to heart catheterization and pathologic changes in the circulatory system. They were the first investigators to measure pulmonary capillary wedge pressures using cardiac catheterization.[32,33]

In 1953, Lategola and Rahn,[34] performed experiments in dogs in which they were the first to use a self-guiding balloon-tipped catheter to measure pressures in the pulmonary circulation. Seventeen years later, Swan et al.[35] at the University of California, Los Angeles, used this technique to assess right heart pressures in humans and in doing so brought this methodology to the bedside, where it is still used today.

During the past 3 decades, much debate has occurred regarding the safety and efficacy of PACs in critically ill adults,[36-45] with multiple calls for a moratorium on PAC usage.[46,47] One randomized, controlled clinical trial underscored the lack of evidence supporting a benefit to therapy directed by PACs compared with standard care,[41] while another showed no significant effect on morbidity and mortality when PACs were used early in patients with sepsis, acute respiratory distress syndrome, or both.[42] An evidence-based review of PAC use reported no added benefit to its routine use, unless it is associated with a defined clinical protocol.[43] Shah and colleagues[44] performed a meta-analysis of 13 randomized clinical trials of the impact of PAC use in critically ill patients and found that it conferred no added benefit, nor did it cause an increase in mortality or hospital days. They concluded that use of evidence-based protocols in combination with PACs may prove to be beneficial. Studies have revealed a significant lack of knowledge and expertise on the part of physicians using PACs, suggesting the tool itself may not be the cause of the problems often associated with the PAC.[48,49] Notably, Friese and colleagues[45] reviewed more than 53,000 patients from the National Trauma Data Bank and found that PACs were used in the management of more severely injured trauma patients. They found that patients who arrived in severe shock and those aged 60 years or older had an associated survival benefit when a PAC was used.[45]

With regard to pediatric patients, the Pulmonary Artery Catheter Consensus Conference, based on a consensus of expert opinions, concluded that the PAC was useful for clarifying cardiopulmonary physiology in critically ill infants and children with pulmonary hypertension, shock refractory to fluid resuscitation and/or low-to-moderate doses of vasoactive medications, severe respiratory failure requiring high mean airway pressures, and on rare occasions, multiple organ failure. They found no data indicating that PAC use increases mortality in children; however, they also failed to find any controlled trials that proved a benefit of PAC use. The panel recommended PAC use for selected patients and called for randomized, controlled trials; a registry of PAC use; and studies to assess the impact of PAC use on cost and duration of ICU/hospital stay.[50] A further review of current studies[51] demonstrated

level B and C evidence for most indications.

Indications

Although still controversial, current indications for PAC use in children include septic shock unresponsive to fluid resuscitation and vasopressor support,[52-54] refractory shock following severe burn injuries,[55] congenital heart disease (CHD),[54] multiple organ failure,[56] and respiratory failure requiring high mean airway pressures.[54,57]

Capabilities of PACs include determination of CVP, pulmonary artery pressure (PAP), and pulmonary artery occlusion pressure (PAOP), also referred to as pulmonary capillary wedge pressure (Pw). PAOP is a measurement of left atrial pressure and left ventricular end-diastolic pressure (when the mitral valve is open). PACs are also used to assess CO, SvO_2, oxygen delivery (DO_2) and consumption (VO_2), and pulmonary vascular resistance (PVR) and systemic vascular resistance (SVR). A fundamental application of the PAC is to examine the function of the right and left ventricles separately. PACs are used to establish diagnoses, guide response to therapy, and assess the determinants of oxygen delivery. PACs are especially helpful in cases of discordant ventricular function and can provide pacing.

One of the most common uses of the PAC in infants and children is monitoring pulmonary pressures during and after repair of CHD. In addition to flow-directed balloon-tipped PACs, transthoracic left atrial catheters are often used in these patients.[58] Use of PACs has altered the management of children with CHD by identifying residual anatomic defects and diagnosing pulmonary hypertensive crisis.[59,60] The ability to monitor PAP provides the means to titrate response to inhaled nitric oxide and other pulmonary vasodilators.[61,62] The lack of response to inhaled nitric oxide may suggest a residual structural anomaly in postoperative patients and indicate the need for repeat cardiac catheterization and/or repair.[62] In addition to monitoring for pulmonary hypertensive crisis, PACs can be used to assess the effects of changes in concentration of inspired CO_2 on mean pulmonary artery pressure (MPAP), pulmonary vascular resistance index (PVRI), and cardiac index (CI).[63]

Monitoring Techniques with the Pulmonary Artery Catheter

The functional features of the PAC are several. Its use as a method of indicator thermodilution, measurement of cardiac output, monitoring, and blood sampling is well documented. Fig. 28.10 demonstrates the expected waveforms as the catheter passes through the cardiovascular system. Technical concepts are important for understanding the calculations needed for optimum use. Refer to Table 28.1 for a summary of the hemodynamic parameters that can be derived from a PAC.

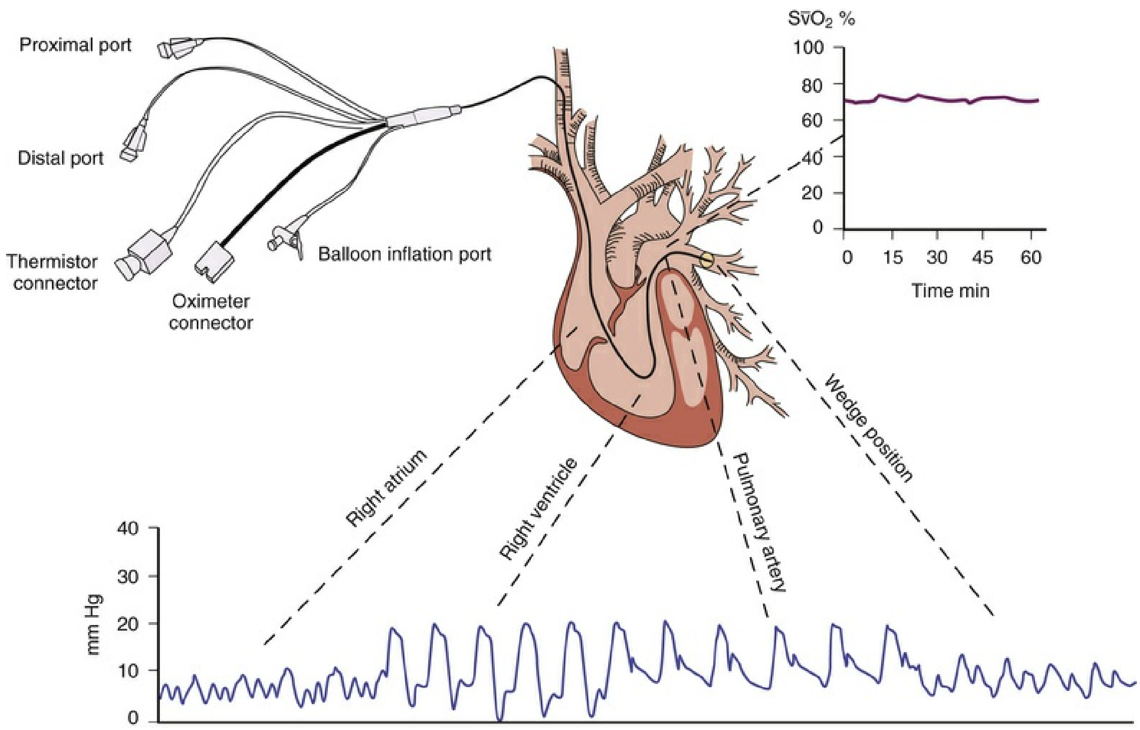

FIG. 28.10 Components and functional features of a thermodilution flow-directed pulmonary artery catheter. The flexible multilumen catheter with the balloon at the distal tip inflated is in the wedge position. The proximal ends of the five lumens are labeled. The distal port is connected to a pressure measurement system for catheter insertion and subsequent monitoring. When the distal tip is within the central venous circulation, the balloon is inflated to enhance flow direction of the tip through the right atrium into the right ventricle and then to the pulmonary artery. Recorded pressures *(lower panel)* correspond to these locations, confirming the course of the catheter. The *last tracing on the right* corresponds to the "wedge" position, commonly reflecting pressure transmitted from the left atrium via the pulmonary veins and capillaries. *Upper right panel* shows an example of a continuous SvO_2 (venous oxygen saturation) tracing from the fiberoptic monitor available on adult-size catheters. (Modified from Daily EK, Tilkian AG. Hemodynamic monitoring. In: Tilkian AG, Daily EK, eds. Cardiovascular Procedures, Diagnostic Techniques and Therapeutic Procedures. St. Louis: Mosby; 1986.)

TABLE 28.1
Hemodynamic Parameters

Parameter	Formula	Normal Range	Units
Cardiac index	CI = CO/BSA	3.5-5.5	L/min/m^2
Stroke index	SI = CI/heart rate × 1000	30-60	mL/m^2
Arterial-mixed venous O_2 content difference	$avDO_2 = CaO_2 - CvO_2$	30-55	mL/L
O_2 delivery	$DO_2 = CI \times O_2$	620 ± 50	mL/min/m^2
O_2 consumption	$VO_2 = CI \times avDO_2$	120-200	mL/min/m^2
O_2 extraction ratio	$ERO_2 = avDO_2/CaO_2$	0.26 ± 0.02	
Arterial oxygen content	$(1.34 \times Hb \times SaO_2) + (PaO_2 \times 0.003)$		mL/L
Venous oxygen content	$(1.34 \times Hb \times SvO_2) + (PvO_2 \times 0.003)$		mL/L
Fick principle	$VO_2 = CO \times (CaO_2 - CvO_2)$		
Systemic vascular resistance index	SVRI = 80 × (MAP – CVP)/CI	800-1600	dyne–sec/cm^5/m^2
Pulmonary vascular resistance index	PVRI = 80 × (MPAP – PAOP)/CI	80-200	dyne–sec/cm^5/m^2
LV stroke work index	LVSWI = SI × MAP × 0.0136	56 ± 6	gm-m/m^2

RV stroke work index	RVSWI = SI × MPAP × 0.0136	0.5 ± 0.06	gm-m/m^2

$avDO_2$, arterial-mixed venous content difference; *BSA,* body surface area in m^2; *CaO_2,* O_2 content of systemic arterial blood in mL/L; *CI,* cardiac index; *CO,* cardiac output; *CvO_2,* O_2 content of mixed venous blood in ml/L; *CVP,* central venous pressure in mm Hg; *DO_2,* oxygen delivery; *ERO_2,* O_2 extraction ratio; *Hb,* hemoglobin; *LVSWI,* left ventricular stroke index; *MAP,* mean systemic arterial pressure in mm Hg; 80 is the conversion factor used for the units in the table; *MPAP,* mean pulmonary arterial pressure in mm Hg; *PAWP,* pulmonary artery wedge pressure in mm Hg, which is approximately equal to the left atrial pressure under many circumstances; *PvO_2,* partial oxygen pressure in mixed venous blood; *PVRI,* pulmonary vascular resistance index; *RVSWI,* right ventricular stroke work index; *SI,* stroke index; *SvO_2,* venous oxygen saturation; *SVRI,* systemic vascular resistance index; *VO_2,* oxygen consumption.

Catheter Placement

PACs typically contain the following ports (Fig. 28.10). The proximal port is located 15 cm from the tip in 5-French catheters and 30 cm from the tip in larger catheters. It opens into or near the right atrium. The proximal port provides access for infusion of fluid or drugs, injection of cold saline solution as indicator (thermodilution method), CVP monitoring, and blood sampling. In infants or small children, PAC placement via the internal jugular or subclavian vein may result in the improper location of the proximal port before the right atrium such that the port lies inside the sheath or outside the body. Therefore it is essential to verify not only the placement of the distal tip in the pulmonary artery but also the location of the proximal port.

The distal port opens at the tip of the catheter. It is used for monitoring PAP and PAOP, blood sampling of mixed venous blood gases, and infusion of fluids. By monitoring pressure continuously through this port during catheter placement, the location of the tip can be determined from the characteristic pressure tracings shown in Fig. 28.10. After placement, PAP should be monitored continuously in order to identify inadvertent migration into the pulmonary capillary bed or "wedged" position. It is important to allow the catheter tip to "float" into the wedged position only when actively measuring PAOP in order to minimize risk of pulmonary artery infarct or rupture.

The balloon inflation port inflates the balloon, which is located 1 cm proximal to the catheter tip. The balloon is inflated for flow-directed catheter placement and PAOP monitoring.

The thermistor is located just proximal to the balloon and connects to a bedside computer to measure changes in the temperature of pulmonary artery blood.

The oximeter uses a fiberoptic-based sensor to continuously measure the SvO_2.

Larger catheters also may have cardiac pacing ports. An adult-sized catheter is available for "continuous" CO determination when coupled with an appropriate bedside computer.

Indirectly Measured Variables

Measurements from PACs include directly and indirectly measured or derived variables. Directly measured variables include CVP, MAP, MPAP, PAOP, CO, SaO_2, and SvO_2. Derived parameters include CI, PVR, SVR, PVRI, and SVRI, as well as SV (in mL/beat) and stroke volume index (SVI; in mL/beat/m^2). Stroke index (SI), or SVI,

normally is 30 to 60 mL/m^2.[64,65]

$$SV = CO/HR \quad \text{Eq. 28.2}$$

$$SVI = SV/BSA \quad \text{Eq. 28.3}$$

Left ventricular stroke work index (LVSWI) and right ventricular stroke work index (RVSWI) normally are 56 ± 6 and 0.5 ± 0.06 gm-m/m^2, respectively.[64,65] Note that all values are for pediatric patients unless otherwise indicated.

$$LVSWI = SI \times MAP \times 0.0136 \quad \text{Eq. 28.4}$$

$$RVSWI = SI \times MPAP \times 0.0136 \quad \text{Eq. 28.5}$$

Measurement of Cardiac Output

CO is the volume of blood pumped by the heart each minute, or SV multiplied by the number of ejections per minute or HR (CO = HR × SV) and often is expressed as CI, which is CO divided by the body surface area (BSA) in m^2. The normal range for infants and children is approximately 3.3 to 6 L/min/m^2.[64,65] Two methods for calculating CO are discussed here: the Fick method and thermodilution.

Fick Method

In 1870, Adolph Fick was the first to study the relationship between blood flow and gas exchange in the lungs using a mathematic model.[66] Fick hypothesized that the amount of oxygen extracted by the body from the blood must equal the amount of oxygen taken up by the lungs during breathing. Fick also reasoned that the flow of blood through the lungs must equal the CO to the remainder of the body in the absence of a shunt. If the amount of oxygen consumed by the body and the amount of oxygen extracted by the body from the blood can be determined, then the CO can be determined. In Fick's time, oxygen consumption was measured using a basal metabolism spirometer, and the oxygen content in arterial and venous blood was measured using a rudimentary method.[66] Although Fick's method remains the gold standard, it is rarely used in the ICU because it is less practical than the more commonly used thermodilution method described in the next section. However, Fick's method is commonly used in the cardiac catheterization laboratory because the required data are readily available in this setting, although oxygen consumption, typically, is estimated.

As noted previously, Fick's equation is based on the assumption that the amount of oxygen extracted by the body from the blood equals the amount of oxygen taken up from the lungs during breathing.

The amount of oxygen extracted by the body from the blood equals the difference in oxygen content of arterial (CaO_2) and venous blood (CvO_2) in mL/L, also referred to as *arterial-mixed venous oxygen content difference* ($avDO_2$), multiplied by the total amount of blood pumped through the lungs or body (CO).

The oxygen content of the blood is a function of the hemoglobin (Hb) concentration of blood in g/dL, the arterial or venous oxygen saturation (SaO_2 or SvO_2) expressed in decimal form, and the arterial or venous partial pressure of arterial oxygen (PaO_2 or PvO_2) in mm Hg. The oxygen-carrying capacity of adult Hb is 1.34 mL O_2 per gram Hb, and the Bunsen solubility coefficient of O_2 in plasma at 37°C equals 0.003. A true SvO_2 is measured in the pulmonary artery; however, in the presence of an intracardiac shunt, SvO_2 should be measured in the SVC.

$$CaO_2 = 10 \times [(1.34 \times Hb \times SaO_2) + (PaO_2 \times 0.003)]$$ **Eq. 28.6**

$$CvO_2 = 10 \times [(1.34 \times Hb \times SvO_2) + (PvO_2 \times 0.003)]$$ **Eq. 28.7**

Note that the units for oxygen content in this chapter are milliliters of oxygen per liter of blood rather than milliliters of oxygen per deciliter of blood, as is in many other sources. (Thus the values for CaO_2 and CvO_2 must be converted to mL/L by multiplying in a correction factor of 10 dL/L.) Expressing oxygen content in these units allows for easy computation of CO, which is expressed as liters per minute.

The $avDO_2$ is the difference between CaO_2 and CvO_2 and normally ranges from 20 to 78 mL/L.[65]

$$avDO_2 = CaO_2 - CvO_2$$ **Eq. 28.8**

As noted earlier, the amount of oxygen extracted (consumed) by the body from the blood equals $avDO_2$ multiplied by the amount of blood that flows through the lungs (Q_P). Assuming Q_P equals the flow of blood through the systemic circulation (Q_S), then Q_P is a measure of CO. (Note that pulmonary and systemic blood flows cannot be assumed to be identical in children with CHD with single-ventricle physiology or with shunts.)

$$O_2\text{extraction} = (CaO_2 - CvO_2) \times CO$$ **Eq. 28.9**

The amount of oxygen taken up by the lungs equals the amount of oxygen consumed by the body. According to Fick, the amount of oxygen extracted by the body from the blood (Eq. 28.10) equals oxygen consumption (VO_2).

$$(CaO_2 - CvO_2) \times CO = VO_2 \quad \textbf{Eq. 28.10}$$

$$CO = VO_2/(CaO_2 - CvO_2) \quad \textbf{Eq. 28.11}$$

As noted in Eqs. 28.6 and 28.7, the amount of dissolved oxygen in blood (PaO_2 or PvO_2) contributes an almost negligible amount to the oxygen content and can be left out for ease of computation. By rearranging Eq. 28.11, a rough estimate of CO can be calculated rather easily at the bedside without use of a PAC:

$$CO = VO_2/(1.34 \times Hb \times (SaO_2 - SvO_2) \times 10) \quad \textbf{Eq. 28.12}$$

Oxygen consumption can be measured using the metabolic cart or taken from standardized tables.[14] Hb concentration can be measured directly. SaO_2 can be taken from the pulse oximeter. SvO_2 can be measured by the oximeter at the distal end of the PAC or determined from a venous blood gas sample from a catheter in the internal jugular or subclavian vein.

These data also can be used to calculate the intrapulmonary shunt fraction, which is the fraction of blood that passes through unventilated areas of lung:

$$Qs/Qt = (CpvO_2 - CaO_2)/(CpvO_2 - CvO_2) \quad \textbf{Eq. 28.13}$$

where CaO_2 is systemic arterial oxygen content and CvO_2 is mixed venous oxygen content.

$CpvO_2$ is the theoretical oxygen content in a normal pulmonary vein and can be calculated using the alveolar gas equation:

$$CpvO_2 = 10 \times [1.34 \times Hb \times SpvO_2 + PpvO_2 \times 0.003] \quad \textbf{Eq. 28.14}$$

where $SpvO_2$ is pulmonary vein O_2 saturation and $PpvO_2$ is pulmonary vein pO_2.

For the normal lung, $PpvO_2$ can be estimated from the alveolar air equation, and $SpvO_2$ is presumed to be 1.0:

$$PpvO_2 = PaO_2 = (PiO_2 - P_{wp}) - PaCO_2/R \quad \textbf{Eq. 28.15}$$

where PaO_2 is alveolar partial pressure of oxygen, PiO_2 is inspiratory pO_2, P_{wp} is vapor pressure of water (47 mm Hg at 37°C), $PaCO_2$ is arterial CO_2, and R is respiratory quotient, which is normally assumed to be 0.8.

The normal shunt fraction is 3% to 7%.

Thermodilution Method

In 1921, Stewart[67] first described an indicator-dilution method for measuring CO. Flow was calculated by measuring the change in concentration of an indicator over time. The "ideal" indicator is "stable, nontoxic, uniformly distributed, and [does] not leave the system between sites of injection and detection. However, it should be rapidly cleared in a single circulation time to prevent recirculation interfering with measurement."[68]

In 1953, Fegler[69,70] demonstrated that a change in the heat content of blood could be used as an indicator for CO measurement. A bolus of cold liquid of a known temperature is injected into or proximal to the right atrium. A thermistor near the PAC tip in the pulmonary artery or a pulmonary artery branch measures a change in the temperature of the blood as the bolus passes by the end of the catheter. A computer calculates the flow by integrating the change in temperature at the thermistor.

The first law of thermodynamics, the conservation of heat, is the fundamental principle underlying thermodilution. Thermodilution makes several assumptions: physiologic conditions must remain constant during the period of observation, all heat exchange occurs between the indicator and the blood without heat loss to the surrounding tissues, mixing of the injectate and blood is complete upstream of the temperature measurement, and the temperature sensor is sufficiently sensitive, accurate, and rapidly responsive to depict accurately the change in temperature over time.

Measurement of CO using the thermodilution method can be understood by examining a modified version of the Stewart-Hamilton equation.[68] V_1 is injectate volume (in mL); Tb is temperature of the pulmonary artery at baseline (in degrees Celsius); Ti is temperature of the injectate (in degrees Celsius); K^1 is the density factor that equals the specific heat of the injectate multiplied by the specific gravity of the injectate, divided by the product of the specific heat and specific gravity of blood; and K^2 is a constant that figures in the dead space of the catheter and the loss of heat from the injectate as it moves through the catheter. The denominator of the equation is the integral of the change in the temperature of the blood (Tb) over time (t):

$$CO = V_1(Tb - Ti)K^1K^2 \Big/ \int \Delta Tb(t)dt \qquad \textbf{Eq. 28.16}$$

The computer generates a CO curve with the area under the curve inversely related to the magnitude of the CO. In settings of low CO, less warm blood flows with the injectate and the injectate stays cooler. The difference between the injectate temperature and that of the blood remains large, and the CO curve has a high domed shape, with a slow return to baseline temperature. In situations of high CO, more pulmonary artery blood flows with the injectate and the temperature of the injectate approaches or equals that of the blood more rapidly. In these situations, because the difference between the final temperature of the injectate and that of the blood is small, the CO curve rapidly returns to baseline following a sharp spike from the cold injectate. In extreme low-flow states, the change in temperature of the injectate resulting from handling alone, before the injectate even enters the catheter from the proximal port, may be greater than the change caused by warming of the

injectate by the flow of blood.

A correction factor is added to the equation to account for warming of the injectate because of handling alone; however, the correction factor may be inaccurate if the injection is too slow or the syringe is held in the injector's hands or too long. Therefore CO readings should be made as quickly as possible and should be repeated until three successive readings are within 15% of each other. Other sources of error include a falsely elevated CO because of inadvertent warming of the thermistor when it is up against the wall of the pulmonary artery. The thermodilution method generally should not be used in patients with an intracardiac shunt; however, if the shunt fraction is less than 10%, the error likely is negligible.[21]

Calculation of Oxygen Delivery and Consumption

Metabolic derangements, such as fever, sepsis, and shock, interfere with oxygen delivery (DO_2) to and consumption by (VO_2) the tissues. The SvO_2 is a measure of the oxygenation of blood returning to the heart. SvO_2 can be measured continuously by a fiberoptic oximeter (see description of PAC ports in the catheter ports section) and normally ranges from 65% to 75%. The oxygen extraction ratio (ERO_2) is $avDO_2$ (see Eq. 28.8) divided by CaO_2 (Eq. 28.11) and usually is approximately 25%[64,65]:

$$ERO_2 = avDO_2/CaO_2 \qquad \textbf{Eq. 28.17}$$

DO_2 also can be expressed as the product of CI and CaO_2 and VO_2 as the product of CI and $avDO_2$. The normal value for DO_2 is 620 ± 50 mL/min/m^2, whereas VO_2 typically ranges from 120 to 200 mL/min/m^2.[64,65]

$$DO_2 = CI \times CaO_2 \qquad \textbf{Eq. 28.18}$$

$$VO_2 = CI \times avDO_2 \qquad \textbf{Eq. 28.19}$$

Interpretation of Waveforms

The waveforms corresponding to the right atrium and the systemic arterial blood pressure were discussed in previous sections. The pressure in the right atrium ranges from approximately 3 to 12 mm Hg. As the PAC passes into the right ventricle, the diastolic pressure drops to 0 to 10 mm Hg and the systolic pressure increases to 13 to 42 mm Hg. As the catheter enters the pulmonary artery, the diastolic pressure increases to 3 to 21 mm Hg while the systolic pressure remains relatively similar to that of the right ventricle, 11 to 36 mm Hg. Once the catheter tip advances into the pulmonary capillary bed and the pulmonary artery is occluded by the inflated balloon, the measured pressure decreases to 2 to 14 mm Hg.[21] By

recognizing the changes in the various tracings, the movement of the catheter tip can be followed through the chambers of the right heart and into the pulmonary circulation, without simultaneous imaging.

The waveforms are affected by the components of the respiratory cycle. As expected, the effects of respiration differ during unsupported breathing (negative pressure) versus mechanical ventilation (positive pressure). During normal unsupported ventilation, PAPs decrease during inhalation and increase during exhalation. In contrast, during mechanical ventilation, PAP increases during inhalation and decreases during exhalation. The cyclical changes induced by the respiratory cycle cause the tracings to take on a sinusoidal pattern once the tip of the catheter enters the thorax. The effects of respiration on PAC determinations can be minimized by measuring pressures at the end of expiration, when pleural pressures are closest to zero.

Because CVP is a measure of preload or filling of the right ventricle, it reflects changes in volume status, right ventricular function, and pulmonary vascular tone. Similarly, PAOP measures filling pressures of the left atrium and ventricle. When the pulmonary artery is occluded, the pressure from the left atrium is transmitted back to the catheter tip. During diastole, when the mitral valve is open and the aortic valve is closed, a continuous fluid-filled column is formed from the catheter tip to the left ventricle and PAOP is equivalent to the left ventricular end-diastolic pressure. In patients with cardiogenic shock, an elevated PAOP may reflect decreased function of the left ventricle. In this situation, rather than providing further fluid resuscitation or preload, increasing contractility or decreasing afterload may be preferable. Afterload is the load that the heart must eject blood against and is inversely related to SV (volume of blood ejected by the heart with each beat) and CO. It is determined by the impedance of the vasculature, ejection pressure, preload, and ventricular wall stress.

According to Laplace's law, ventricular wall stress *(T)* is proportional to ventricular transluminal pressure *(P)* (Intraluminal pressure – Extraluminal pressure) and radius *(r)* and is inversely related to twice the wall thickness *(t):*

$$T = P \times r/2t \qquad \textbf{Eq. 28.20}$$

For a given pressure, wall stress is increased by an increase in radius (ventricular dilation); therefore volume administration may increase ventricular diameter and consequently wall stress. Thus afterload is preload dependent. Similarly, during spontaneous breathing the transluminal pressure and consequently the wall stress increase, whereas during mechanical ventilation (positive pressure) the transluminal pressure and wall stress both decrease. Ventricular hypertrophy increases wall thickness and therefore decreases wall stress.

Resistance

To understand resistance, returning to Ohm's law is helpful: voltage (V) varies directly with resistance (R) and current (I):

$$V = IR \qquad \textbf{Eq. 28.21}$$

Rearranging Eq. 28.21 by substituting pressure for voltage and flow for current gives Eq. 28.22:

$$R = (Pin - Pout)/Q \qquad \textbf{Eq. 28.22}$$

where *R* is resistance, *Pin* is pressure going into a vessel, *Pout* is pressure exiting the vessel, and *Q* is flow. According to Poiseuille's law, the resistance of flow through a tube varies directly with the viscosity of the fluid and the length of the tube and is inversely proportional to the radius to the fourth power multiplied by pi (π):

$$R = 8\eta l/\pi r^4 \qquad \textbf{Eq. 28.23}$$

where η is viscosity, *l* is length, and *r* is radius. Unfortunately, Poiseuille's law assumes uniform viscosity, length, and radius, none of which holds true in the case of the pulmonary or systemic circulation; however, the principles behind the law are valuable in understanding the major determinants of resistance.

By substituting the appropriate values into Eq. 28.20, the formulas for SVR and PVR can be derived. CO is substituted for Qs and Qp in the absence of a right-to-left or left-to-right shunt or single-ventricle physiology. In the case of the equation for PVR (Eq. 28.25), PAOP is substituted for pulmonary vein pressure in determining Pout:

$$SVR = (MAP - CVP)/CO \qquad \textbf{Eq. 28.24}$$

$$PVR = (MPAP - PAOP)/CO \qquad \textbf{Eq. 28.25}$$

SVR and PVR are measured in mm Hg × minute × L^{-1} (or mm Hg/L per min). These units also are referred to as hybrid resistance units or Wood units after the cardiologist Paul Wood.[18] By multiplying by 80, hybrid resistance units or Wood units can be converted to the centimeter-gram-seconds (cgs) system, where resistance is measured as dynes sec/cm^5, also known as absolute resistance units.

PVR and SVR often are indexed for BSA (in square meters). The systemic vascular resistance index (SVRI) and pulmonary vascular resistance index (PVRI) are measured as dynes sec/cm^5/m^2:

$$SVRI = 80 \times (MAP - CVP)/CI \qquad \textbf{Eq. 28.26}$$

$$PVRI = 80 \times (MPAP - PAOP)/CI \qquad \textbf{Eq. 28.27}$$

SVRI usually is 800 to 1600 dynes sec/cm^5/m^2 in children[65,66] and 2180 ± 210 in adults.[71]

Calculation of Intracardiac Shunt

If the oxygen saturations throughout the cardiopulmonary circulation are known, derivation of the values for the ratio of pulmonary to systemic blood flow or intracardiac shunt (Qp/Qs) is possible:

$$Qp = VO_2/(1.34 \times 10 \times Hb\,(SpvO_2 - SpaO_2)) \qquad \textbf{Eq. 28.28}$$

$$Qs = VO_2/(1.34 \times 10 \times Hb\,(SaO_2 - SvO_2)) \qquad \textbf{Eq. 28.29}$$

$$Qp/Qs = (SaO_2 - SvO_2)/(SpvO_2 - SpaO_2) \qquad \textbf{Eq. 28.30}$$

where $SpvO_2$ is oxygen saturation in the pulmonary vein and $SpaO_2$ is oxygen saturation in the pulmonary artery. In the absence of severe intrapulmonary shunt, $SpvO_2$ approaches 98% to 100%. In a complete mixing lesion, $SpaO_2$ and SaO_2 should be equal by definition, enabling SaO_2 to be substituted for $SpaO_2$.

Novel Monitoring Devices

Recent application of novel devices has started bridging invasive and noninvasive monitoring of cardiac output. Modalities such as pulse wave analysis,[72] Doppler ultrasound,[73] bioimpedance,[74,75] and electrical velocimetry[76,77] have been validated to varying degrees and introduced into limited pediatric intensive care practice. These methods are noninvasive or relatively noninvasive in nature and often use algorithms that do not require frequent calibration. Their use may be limited by an understanding of the appropriateness of the data that they provide. Although the long-term utilization of such devices is not yet established, their relative ease of use or in placement, often using in-situ central venous catheters and arterial lines, in comparison with the PAC, as well as independence of influence from mechanical ventilation and additional monitoring capabilities, make them attractive to practitioners.

Conclusions

Invasive hemodynamic monitoring provides the intensivist with valuable information regarding the condition of critically ill children. Correct interpretation of this information is necessary to optimally aid in the management of these patients whose condition is often complex. New noninvasive monitoring modalities are emerging that may eventually supplant the need for these invasive measurements, but thus far invasive monitoring remains a cornerstone of pediatric critical care

medicine.

CHAPTER 29

Assessment of Cardiovascular Function

Melvin C. Almodovar, Thomas J. Kulik, John R. Charpie

PEARLS

- Cardiovascular assessment and monitoring in the pediatric intensive care unit require careful integration of physical findings, laboratory studies, and electronic data to make appropriate therapeutic decisions.
- Noninvasive monitoring includes physical examination, chest radiography, echocardiography, blood pressure monitoring, and pulse oximetry. Invasive monitoring includes intravascular and intracardiac monitoring, cardiac output measurements (thermodilution or Fick method), and laboratory studies.
- Appreciating the quantity of therapy required to achieve and sustain adequate systemic oxygen delivery and perfusion pressure is useful for the clinician to understand the patient's overall condition, discern the patient's trajectory, and anticipate associated consequences of current management choices.
- Management of patients with single-ventricle physiology (such as the neonate with hypoplastic left heart syndrome) poses several unique challenges to the cardiac intensivist, including optimization of pulmonary-to-systemic blood flow ratios for best systemic oxygen delivery.

Pediatric patients undergoing surgical treatment for congenital heart disease (CHD) or those with severe systemic illnesses such as sepsis and other causes of multiple organ system failure commonly have impaired cardiovascular function.[1,2] In addition to treating the primary disease process, the pediatric intensivist should use strategies to reliably assess and monitor cardiovascular function, which specifically involve assessing adequacy of oxygen delivery (DO_2) and systemic perfusion pressure, the primary determinants of tissue oxygenation.

Cardiovascular Function

The function of the heart and vasculature is to deliver oxygen (O_2) and other

nutrients to various tissues in order to meet the metabolic demands of the organism. Mild to moderate depression of DO_2 is normally compensated by augmented O_2 extraction at the tissue level, thereby maintaining a stable level of oxygen consumption (VO_2). When DO_2 falls below some critical level, this compensatory mechanism fails and a state of O_2 supply dependency exists[3] such that any further drop in DO_2 leads to a parallel fall in VO_2.[4-6] Under a state of supply-dependent O_2 consumption, affected tissues and organs attempt to maintain homeostasis partly through anaerobic metabolism. Several studies suggest the initial metabolic response to hypoxemia or decreased DO_2 differs between the newborn and older ages and varies among different vascular beds. In adults at rest, DO_2 is in great excess of VO_2. This "O_2 surplus" means moderate reductions of O_2 transport are generally well tolerated without compromise of VO_2. In contrast to the adult, the metabolism of the newborn may be particularly susceptible to modest alterations in O_2 transport because of the high resting demands for O_2, the ease with which these demands can be increased by small environmental changes, and the apparently limited reserve for augmenting cardiac output (CO) or O_2 extraction acutely.[7,8] Thus it is crucial that cardiovascular assessment and monitoring in the pediatric intensive care unit (PICU) involve continuous and reliable evaluation of the adequacy of systemic perfusion and DO_2 in order to select appropriate hemodynamic support strategies.

Quantity of Therapy

If one considers hemodynamic monitoring not only in terms of DO_2 and perfusion pressure but also in terms of what therapy is required to produce a given level of tissue oxygenation, one gains a much better understanding of the overall "condition" of the patient. It is therefore important to monitor not only DO_2 and perfusion pressure but also the "quantity of therapy" (QOT) needed to procure and maintain adequate tissue oxygenation. Consider two hypothetical 6-month-old infants, Destiny and Dakota, 2 hours after repair of tetralogy of Fallot. They have identical (and adequate) DO_2 and perfusion pressure, but Destiny has a left atrial (LA) pressure of 6 mm Hg and a right atrial (RA) pressure of 8 mm Hg, whereas Dakota has received volume infusion to achieve an LA pressure of 6 mm Hg and an RA pressure of 15 mm Hg. Assuming that the levels of intravascular volume provided are exactly those needed to achieve the (identical) DO_2 values and perfusion pressures, it is clear that the physiologies of these two patients are different. The clinician who has learned what to expect relative to the QOT in any given set of circumstances will find Dakota's sufficient tissue oxygenation only mildly reassuring and asks: Is there substantial residual right ventricular (RV) outflow tract obstruction or another problem or problems that I need to know about? Will Dakota have sufficient DO_2 in 10 hours when post–bypass myocardial depression is at its worst? Might additional therapy secure adequate DO_2 at a lower filling pressure, thereby minimizing adverse effects of systemic venous hypertension? As this example illustrates, the QOT concept is useful for three reasons:

1. The QOT is, in part, a function of the patient's overall “condition” and can reflect anatomic or physiologic problems that require further exploration.

2. Physiologic trajectory is key, especially early in the course of certain illnesses or after cardiopulmonary bypass, when DO_2 predictably declines over the first 12 hours.[2] Taking into account the QOT relative to tissue oxygenation at any point in time helps one better estimate the likelihood of the need for augmented support (eg, mechanical support of the circulation) as time passes.

3. Some therapies (eg, fluid infusion to obtain high filling pressure, or high airway pressure), while helpful at a point in time, can be pernicious over the longer run: High venous pressure, especially in infants, causes third spacing of fluid, and the effect of ventilator-associated lung injury on lung function can be devastating. By using high central venous or airway pressures, the intensivist is, in effect, incurring a debt to secure short-term perfusion that will have to be repaid later. Experienced clinicians always take the QOT into account in their work, thus influencing their level of concern about a patient and guiding subsequent timing and choice in adjusting therapy.

Almost any form of therapy might be included in the QOT concept, but in this chapter we focus on medical therapies that have the most important effect on hemodynamics, including DO_2 and perfusion pressure. These therapies include inotropic/vasoactive agents, volume infusion, and airway pressures used during mechanical ventilation. The amount of inotropic and vasoactive drugs administered, assuming that they are used appropriately, seems to be a crude indicator of patient illness.[2] Volume infusion to achieve adequate filling pressure is required even for the normal heart, but the QOT concept applies when higher than normal filling pressure is needed to maintain adequate CO. The consequences of high filling pressures are body edema (especially in infants), pleural and other cavity space effusions, and pulmonary edema. If high venous pressure is coupled with systemic hypotension (eg, with a “failing” Fontan circulation), there may be critically reduced transtissue perfusion pressure with a potentially negative impact on cerebral and splanchnic perfusion.

With respect to mechanical ventilation, the need for high mean airway pressure (P_{aw}) is most commonly a reflection of lung disease, but pulmonary edema on a hydrodynamic basis may occasion the use of high P_{aw} for optimal lung recruitment. High P_{aw} can reduce venous return to the heart, increase pulmonary vascular resistance (PVR), and contribute to ventilator-associated lung injury.

Variables That Determine Tissue Oxygenation

Tissue oxygenation is directly related to both DO_2 and systemic arterial blood pressure (SAP). DO_2, the quantity of O_2 delivered to the tissues per minute, is the product of systemic blood flow (SBF), which equals CO except in patients with certain cardiac malformations, and arterial O_2 content:

$$DO_2\ (mL/min) = 10 \times CO\ (L/min) \times CaO_2\ (mL/100\ mL\ blood),$$

where *CO* is cardiac output or SBF in L/min or L/min/m^2 and *Ca*O_2 is quantity of O_2 bound to hemoglobin plus the quantity of O_2 dissolved in the plasma in arterial blood. The O_2 content of arterial blood (mL O_2/dL blood) equals:

$$CaO_2 = (SaO_2 \times Hgb \times 1.36) + (PaO_2 \times 0.003)$$

where *Sa*O_2 is arterial O_2 saturation, *Hgb* is hemoglobin concentration (g/dL), *1.36* (constant) is the amount of O_2 bound per gram of hemoglobin (mL) at 1 atm of pressure, *Pa*O_2 is arterial partial pressure of O_2, and *0.003* (constant) multiplied by the PaO_2 equals amount of O_2 dissolved in plasma at 1 atm. The quantity of dissolved O_2 is generally considered to be negligible in the normal range of PaO_2. Hypoxia, because of poor gas exchange within the lungs (ie, intrapulmonary shunt), or in the setting of CHD with right-to-left shunting, is an important determinant of blood O_2 content.

CO is the product of stroke volume (quantity of blood ejected per beat) and heart rate, and SAP is determined by CO and systemic vascular resistance (SVR). The four primary determinants of cardiac function are preload (which determines the precontractile lengths of the myofibrils); end-systolic wall stress (function of systemic blood pressure and physical characteristics of the arterial system, ventricular wall thickness, and chamber dimension); myocardial contractility; and heart rate. These determinants of ventricular function can be altered by many factors in the intensive care setting. Preload, or end-diastolic volume, is affected by ventricular compliance (rate and extent of cardiomyocyte relaxation and cardiac connective tissue), intravascular volume, and intrathoracic pressure. Expansion of the heart resulting from transmural filling pressure, rather than the LA pressure per se, determines the force of contraction. Therefore intrathoracic (or intrapericardial) pressure is a key determinant of preload. Ventricular hypertrophy, vasodilator and diuretic therapies, and positive pressure mechanical ventilation all adversely affect preload. Similarly, cardiac function is inversely related to afterload, or end-systolic wall stress. Anatomic obstructions and systemic or pulmonary hypertension may negatively affect ventricular systolic and diastolic function. Excessively fast or slow heart rates and inappropriately timed atrial contraction (relative to ventricular systole) may negatively affect ventricular function. Finally, myocardial contractility is often negatively affected by the following factors: hypoxemia, acidosis, hypomagnesemia, hypocalcemia, hypoglycemia, hyperkalemia, cardiac surgery, sepsis, and cardiomyopathies.

Monitoring Tissue Oxygenation

CO can be assessed qualitatively by physical examination and other modalities and quantitatively by a variety of techniques using invasive and noninvasive devices, laboratory data, and other clinical indicators. DO_2 is easily derived if systemic blood

flow can be measured, but it is only indirectly inferred if this information is lacking.

Qualitative Assessment of Cardiac Output

Physical Examination

The physical examination is often the initial and the most common technique used to assess and monitor cardiovascular function. Significantly diminished CO may manifest as diminished peripheral pulses, cool or mottled extremities, and delayed capillary refill. However, certain clinical signs of low CO may be unreliable depending on the particular diagnosis. For example, in the context of cardiac lesions associated with a large arterial pulse pressure (eg, severe aortic insufficiency and aortopulmonary shunts), peripheral pulses may be increased despite low CO and reduced systemic DO_2. Patients in septic shock are often peripherally vasodilated and warm despite hypotension and reduced tissue DO_2. Impaired oxygenation may present as cyanosis of the skin, lips, and/or nail beds. Central cyanosis from either cardiac or respiratory causes results from arterial O_2 desaturation. In contrast, peripheral cyanosis results from vasoconstriction and low blood flow at the microcirculatory level. In some patients, cyanosis is a relatively subtle physical finding, particularly if the patient is anemic or has a dark complexion. Hydration status can be assessed by skin turgor, dryness of mucous membranes, and fullness of the anterior fontanel (in infants), but these manifestations of hydration status relate mostly to interstitial fluid and may poorly reflect intravascular volume, which must be directly measured.

Cardiac auscultation for abnormal heart sounds, including valve clicks, rubs, gallops, and murmurs, may provide the first indication of a significant functional or structural cardiac abnormality, although these sounds do not directly reflect DO_2. Unfortunately, the lack of a heart murmur, especially in low CO states, does not necessarily rule out a significant residual cardiac lesion. The presence of crackles on pulmonary auscultation, particularly in the older pediatric patient, may signify pulmonary edema. However, crackles are nonspecific and may be caused by lung disease or fluid overload, in addition to disorders of cardiac structure or function. Finally, jugular venous distension and hepatomegaly are indicative of high right-sided filling pressures often associated with RV dysfunction.

Chest Radiography

Although the chest radiograph is of little value in assessing a patient's hemodynamic profile per se, it may be helpful for assessing certain aspects related to cardiovascular status. Provided the chest radiograph is technically adequate, the clinician can assess heart size, contour and configuration, pulmonary vascularity, pleural effusions, lung parenchyma, and abdominal situs. Some of these findings, when abnormal, may help determine the etiology of cardiovascular dysfunction. Increased pulmonary arterial vasculature may be indicated by enlarged pulmonary arteries in the hila that radiate toward the periphery of the lung. Conditions that increase pulmonary blood flow (PBF, or Q_p) at least twice normal also increase the size of the pulmonary arteries. Increased pulmonary capillary pressure may be inferred by the presence of pulmonary edema. The edema may present as a “fluffy” hilum but may have a more diffuse granular appearance in neonates. Pleural

effusions may accompany pulmonary edema, particularly in conditions associated with poorly compensated congestive heart failure. Increased pulmonary venous markings are indicative of elevated pulmonary venous pressures of any cause, although usually from decreased left ventricular compliance or obstruction in the pulmonary veins or left atrium.

In the early postoperative period, the most important information obtained from the chest radiograph is (1) the positions of the endotracheal tube, chest tubes, and intracardiac lines; (2) the presence of extrapulmonary fluid or air; and (3) the presence of pulmonary edema. The cardiothoracic ratio gives a quantitative estimate of cardiac size, which is obtained by dividing the transverse measurement of the cardiac shadow in the posteroanterior view by the width of the thoracic cavity. Cardiomegaly is present if this value is greater than 0.5 in adults and 0.6 in infants. Although useful for assessing left ventricular (LV) enlargement, the cardiothoracic ratio is not as sensitive to RV enlargement. RV enlargement results in lateral and upward displacement of the cardiac apex on the posteroanterior view and filling of the retrosternal space on the lateral view. It is perhaps more important to know what the chest radiograph may not reveal; significant cardiac problems, such as constrictive pericarditis, acute fulminant myocarditis, and even acute pericardial tamponade are often associated with a normal-sized heart on a chest radiograph.

Quantitative Assessment of Cardiac Output

Quantitative measures of CO in the ICU can be obtained by a variety of techniques, including the Fick method, thermodilution, dye dilution techniques, and Doppler echocardiography. Each of the first three methods applies a similar principle of dilution of an indicator: O_2, cold, or indocyanine green dye, respectively. The change in concentration of a substance is proportional to the volume of blood in which it is being diluted. In general, thermodilution is the method most widely used in the intensive care setting. However, for conditions of low CO, the Fick method is more reliable than the thermodilution or dye dilution techniques. Conversely, the Fick method is less accurate in conditions of high systemic blood flow because of difficulty in measuring narrow arteriovenous O_2 differences in the blood.

Thermodilution Technique

The thermodilution technique requires use of a specialized pulmonary artery (PA) catheter. CO is calculated by injecting a known volume of iced water or saline solution into the right atrium (proximal catheter port) and measuring the temperature change at the catheter tip in the PA. CO is calculated by the following equation:

$$CO = 1.08 \times V_i (T_b - T_i) / e_0 T_b(t) dt$$

where V_i is injectate volume (mL), T_b is temperature of blood, T_i is injectate temperature, and $T_b(t)dt$ is area under the curve. In general, thermodilution CO measures are performed using a completely automated system, and the calculations are performed by a computer. This method (as with any indicator dilution method)

requires complete mixing and thus is most accurate in situations where a mixing chamber is located proximal to the thermistor. It is generally used only in patients who do not have intracardiac or great vessel–level shunts or an insufficient valve between the injection site and the sampling site. The injection must be made rapidly because a slow injection will give a falsely elevated CO. Possible sources of error with this method include inaccurate measurement of the volume of injectate or temperature of the blood or injectate, close approximation of the thermistor to a vessel wall, and inadequate mixing, as is sometimes seen in venous systems with low flow.

Fick Method

According to the Fick principle, CO equals O_2 consumption divided by the arteriovenous O_2 content difference:

$$CO = VO_2/(CaO_2 - CvO_2)$$

where VO_2 is O_2 consumption (mL/min) and CaO_2 and CvO_2 are arterial and venous O_2 content (mL O_2/100 mL blood), respectively. Care must be taken to select the appropriate sampling site for a true mixed venous blood sample. With a normal heart, the best site to obtain a mixed venous sample is within the PA. If a left-to-right shunt is present, however, the mixed venous site should be the cardiac chamber proximal to the site of the shunt. When a site other than the PA is used for the mixed venous site, the resultant value for arteriovenous O_2 difference is a less reliable reflection of the absolute CO, but it can be used for serial observations and for monitoring response to therapy over time.

Because measuring VO_2 in the intensive care setting requires special equipment and is somewhat cumbersome, the arteriovenous O_2 difference is often used as an indirect measure of CO. A wide arteriovenous O_2 difference generally reflects a low CO and indicates a large O_2 extraction by the tissues, whereas a narrow arteriovenous O_2 difference usually reflects a high CO. Unfortunately, studies suggest VO_2 is quite variable for any individual patient in an intensive care setting.[9] Furthermore, mixed venous O_2 saturation (and, hence, arteriovenous O_2 difference) may be misleading in patients with decreased tissue O_2 extraction.[10,11]

Doppler Echocardiography

Doppler techniques can be used to measure CO using the mean velocity of systolic flow, heart rate at the time of measurement, and cross-sectional area of the artery in which measurements are being made (usually the ascending aorta):

$$CO = A \times V \times HR$$

where *A* is the area of the orifice, *V* is integrated flow velocity, and *HR* is heart rate. To determine the integrated flow velocity, the area under the Doppler curve must be measured. The area of the aortic orifice is commonly obtained by measuring the

aortic diameter from the two-dimensional image, where A = 0.785 ∞ d2. This technique requires special care for accurate Doppler interrogation of blood flow and is seldom used in the critical care unit.

Pulse Oximetry

Pulse oximetry measures the quantity of hemoglobin saturated with O_2 in peripheral arterial blood. It depends on two principles: (1) Oxygenated and reduced hemoglobin have different absorption spectra, and (2) at constant light intensity and hemoglobin concentration, O_2 saturation of hemoglobin is a logarithmic function of the intensity of transmitted light (Beer-Lambert law). Two wavelengths of light that have different absorption spectra for reduced hemoglobin and oxyhemoglobin are transmitted from the light-emitting diodes through the arterial bed. Light absorption at the two wavelengths is compared, yielding the ratio of oxyhemoglobin to reduced hemoglobin, or the O_2 saturation. Pulse oximeters have a high potential for error at saturations below 80%.[12] Furthermore, the O_2 dissociation curve flattens out at the high range so that at saturations greater than 95%, large changes in PaO_2 accompany small changes in saturation. This phenomenon should be kept in mind when monitoring premature infants, for whom it is important to avoid hyperoxia.

Other Measures of DO_2

Acid-Base Status

When tissue hypoxia occurs and affected tissues and organs resort, in part, to anaerobic metabolism, increased production of lactate, CO_2, and hydrogen ions occurs. The anion gap, the difference in unmeasured serum anions and unmeasured serum cations, can yield information regarding the cause of metabolic acidosis. If the anion gap is normal (8 to 16 mEq/L), loss of bicarbonate has occurred, usually via the kidneys or gastrointestinal tract, or rapid dilution of the extracellular fluid has occurred.

Blood Lactate

Blood lactate concentration is a laboratory measure that indirectly reflects perfusion.[13,14] Blood lactate measurements are extensively used for monitoring and evaluating response to therapy. We observed that initial absolute blood lactate levels were less important than the temporal trend in lactate concentrations for predicting mortality in postoperative cardiac patients.[15] Unfortunately, the specificity of blood lactate is imperfect and may lack sensitivity for detecting supply-dependent O_2 consumption, particularly if it is only regional. In addition, blood lactate depends on hepatic metabolism and the rate of production and clearance.

Gastric Tonometry

Gastric tonometry, a technique available for clinical use in adult and some pediatric ICUs, allows indirect assessment of perfusion by measuring gut intramucosal pH or partial pressure of carbon dioxide.[16,17] It may have an advantage over blood lactate concentration in that it can uncover regional hypoxia and hypoperfusion involving the gut and can be adapted for continuous online measurement.[17] Nonetheless, this

technique assumes that a critical reduction in O_2 transport manifests in the splanchnic circulation before it can be detected systemically (probably a reasonable assumption), and tonometric methods are not entirely noninvasive.

Urine Output

Urine output generally reflects CO, but oliguria may occur in the first 24 hours after open heart surgery, especially in neonates, even in the context of good CO and blood pressure. It is therefore important to consider urine output in the context of other indicators of organ perfusion and not as an isolated variable. It should also be noted that the kidneys are quite sensitive to perfusion pressure and that good systemic blood flow coupled with low systemic arterial pressure (due to low SVR) may adversely affect urine output more than other measures of tissue perfusion.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS), a noninvasive technique that has been applied to assess systemic and regional oxygen transport in several clinical and laboratory studies,[18-26] is gaining acceptance, particularly in patients with CHD, as a means of trending regional DO_2 or as a surrogate for mixed venous O_2 saturation or systemic DO_2.[27] Abdominal site NIRS has been shown to correlate with simultaneous intramucosal pH measurements by gastric tonometry in neonates and infants with CHD undergoing catheter-based or surgical intervention.[28] In an experimental setting in which DO_2 is controlled, NIRS has been used to correlate cytochrome *aa3* (the terminal link in the electron transport chain responsible for mitochondrial respiration), VO_2, and lactate flux.[23] Thus NIRS has the potential to identify a critical regional reduction in O_2 transport at the cellular level.

Systemic Arterial Blood Pressure

Invasive Blood Pressure Monitoring

Intravascular pressure monitoring is often essential in the management of critically ill neonates and infants in the ICU. Typically, an end-hole catheter is inserted into a vessel (or cardiac chamber) and connected to a pressure transducer by a coupling system composed of fluid-filled extension tubing, a stopcock for withdrawing blood and balancing the transducer to atmospheric pressure, and a continuous infusion device to flush out blood and air. The transducer translates pressure into an electrical signal that can be processed through a preamplifier into a waveform and numerical display on a monitor. The pressure transducer must be properly calibrated, dampened, and positioned (at mid-chest level). Inaccurate measurements can occur for a variety of reasons.

In the pediatric population, blood pressure is age dependent and is a relatively insensitive marker of CO and DO_2. Because blood pressure is the product of CO and SVR, hypotension may result from diminished CO and/or decreased SVR.[29] Because the treatment options are different, distinguishing low CO from low SVR is important.

Noninvasive Blood Pressure Monitoring

The auscultatory method of blood pressure measurement with a cuff and pressure gauge is difficult if access to the patient is limited, if the patient is small or uncooperative, and when frequent recordings are required. Therefore two techniques, Doppler and oscillometric measurements, have been developed. The Doppler technique uses a Doppler ultrasound probe that is applied to the radial or brachial artery. A cuff wrapped around the upper arm is inflated until the audible Doppler signal is obliterated and then deflated until the signal first becomes audible again (systolic blood pressure). This method has been validated in low-flow states and in small children.[30] The oscillometric method has the advantage of being readily automated. The device for indirect noninvasive mean arterial pressure (Dinamap) is based on the principle that blood flow through a vessel produces oscillation of the arterial wall that may be transmitted to an inflatable cuff encircling the extremity. As cuff pressure decreases, a characteristic change occurs in the magnitude of oscillation at the levels at which systolic, diastolic, and mean pressures are registered. Accuracy of Dinamap blood pressures has been validated in children, and it correlates well with direct intravascular radial artery pressures.[31] The accuracy of these two techniques relates to the cuff size. If the cuff is too narrow, the pressure recorded may be erroneously high; if the cuff is too wide, the pressure recorded may be too low. Both techniques are unreliable and inadequate in patients with low CO, hypotension, dysrhythmias, significant edema, or systemic vasoconstriction.

Central Venous or Intracardiac Pressure Monitoring

Pressures can also be measured in the cardiac chambers or in the pulmonary vasculature. However, the necessity for intravascular or intracardiac lines should always be carefully considered, and they should be removed as soon as the clinical condition permits. The placement of relatively large catheters in small vessels for prolonged periods carries a risk of thrombosis and systemic thromboembolism.

Central venous access affords the opportunity to measure central venous pressure (CVP), deliver drugs or high osmolarity nutritional solutions, and repeatedly sample blood to monitor venous O_2 saturations and for other laboratory studies. Intraarterial lines offer the opportunity to continuously monitor arterial pressure and for intermittent blood gas analysis.

Intravascular pressures provide information about ventricular preload and afterload. RV preload is assessed by the CVP. The CVP is determined by a variety of factors, including patient age, preoperative status (ie, a patient with RV hypertrophy and increased RA pressure), cardiac performance, intrathoracic pressure, blood volume, vasopressor therapy, and status of the pericardium. The CVP *a wave* reflects atrial contraction, and the *v wave* reflects atrial filling. Serial measurements of CVP are frequently used to evaluate the response to fluid administration. RV afterload can be assessed using a PA catheter. This catheter is particularly important for monitoring pulmonary artery pressure and therapeutic response to vasodilators in patients with elevated PVR. The PA wedge pressure reflects LA pressure (in the absence of pulmonary vein stenosis). In the postoperative cardiac patient, a direct LA line can be placed to directly assess LV preload. LV afterload is assessed by measurement of SAP, provided no LV outflow tract obstruction is present.

Assessing Variables That Affect the Quantity of

Therapy

If it is important to take into account the QOT needed to secure adequate tissue perfusion, it follows that one would like to assess the variables that affect the QOT. Table 29.1 summarizes the effect of abnormalities of cardiovascular and pulmonary function on QOT. What follows is a brief description of how these cardiovascular variables may be assessed in the critical care unit.

TABLE 29.1

Cardiovascular Function and Quantity of Therapy (QOT)

Cardiac System Variable	Impact on QOT
Cardiac Function	
↓ Ventricular systolic function	↑ Filling pressure, ↑ inotropic/pressor support
↓ Ventricular diastolic function	↑ Filling pressure, ↑ pressor support
Abnormal rhythm	↑ Filling pressure, ↑ inotropic/pressor support
Intracardiac structural lesions (↓ efficiency)	↑ Filling pressure, ↑ inotropic/pressor support
Single ventricle with A-P shunt (↓ efficiency)	↑ Filling pressure, ↑ inotropic/pressor support
Peripheral Vasculature	
↑ SVR	↑ Ventricular work → ↑ filling pressure, ↑ inotropic/pressor support
↓ SVR	↑ Filling pressure, ↑ inotropic/pressor support
↑ PVR 2 ventricles	↑ Ventricular work → ↑ filling pressure, ↑ inotropic/pressor support
Aortopulmonary shunt	↓ PBF → ↓ O_2 → ↑ filling pressure, ↑ inotropic/pressor support
Bidirectional Glenn	↑ SVC pressure
Fontan	↑ filling pressure, ↑ inotropic/pressor support
Vascular Function	
"Leaky" vascular bed → edema → volume infusion → edema	↑ Filling pressure, ↑ inotropic/pressor support
Pulmonary Function	
↓ Lung compliance, ↓ gas exchange	↑ Airway pressure → ↓ venous return → ↑ systemic venous pressure, barotrauma

Ventricular Systolic Function

Precise measurement of ventricular systolic function is difficult,[32] especially in the critical care setting. A commonly used surrogate is the echocardiographic demonstration of ventricular wall excursion/shortening. LV shortening and ejection fractions can be measured using echocardiography with reasonable accuracy, but these variables are influenced by preload and afterload and by inotropic conditions. RV morphology makes echocardiographic measurement of systolic function even more problematic, despite a variety of described techniques to assess this variable.[33] For either ventricle, most often one resorts to a qualitative assessment of ventricular wall excursion as a crude estimate of systolic function. Although cardiac magnetic resonance angiography/magnetic resonance imaging can accurately measure LV and RV ejection fraction, it is often of limited practical utility in the critically ill pediatric patient.

Ventricular Diastolic Function

Ventricular diastolic function is also difficult to measure precisely. In the critical care unit, diastolic dysfunction is usually manifested as a need for increased filling pressures for a given magnitude of ventricular output. Echocardiography sometimes

will demonstrate an apparently underfilled ventricle despite adequate or high filling pressures, but most often a lack of compliance is inferred from high filling pressures alone. Echocardiographic measures of ventricular compliance exist, but many clinicians have found them to be of limited practical value. It is important to emphasize that *transmural filling pressure*, not atrial pressure per se, is what determines diastolic filling; elevated pericardial or intrathoracic pressure will reduce ventricular filling for any given atrial pressure.[34]

Rhythm Disturbance

A variety of abnormal rhythms can decrease systemic perfusion and therefore lead to increased QOT. A surface electrocardiogram may be sufficient to delineate the type and mechanism of an arrhythmia; however, especially with tachycardia, all too often one cannot clearly discriminate P waves from the T and QRS deflections. The use of atrial leads in conjunction with limb leads can be exceedingly helpful for both diagnosing and treating arrhythmias in postoperative patients. Alternatively, esophageal electrodes sometimes can be helpful, although they are somewhat cumbersome to use (and cannot always effect atrial capture). It is important to frequently and carefully reassess the rhythm because significant changes (eg, from sinus rhythm to junctional ectopic tachycardia) may escape casual detection.

Abnormal Systemic Vascular Resistance

Abnormal systemic vascular resistance is determined by the following equation:

$$SVR = (SAP - CVP)/CO$$

where *SAP* is mean systemic arterial pressure (mm Hg), *CVP* is mean central venous pressure (mm Hg), and *CO* is cardiac output, usually indexed to surface area ($L/min/m^2$).

Increased SVR can be useful when CO is insufficient for adequate systemic perfusion pressure with normal SVR. On the other hand, SVR increased beyond that needed for adequate SAP increases systemic ventricular afterload and may therefore negatively affect CO.[35] For reasons discussed in the following section on single-ventricle physiology, increased SVR may also result in excess PBF in patients with an aortopulmonary shunt. Finally, increased SAP in a newly postoperative patient may contribute to excessive bleeding. In contrast, low SVR can cause systemic hypotension despite adequate or supranormal CO. Anecdotal observations and some published information indicate that low SVR may occur after cardiac surgery, as well as with other systemic illnesses (eg, sepsis).

As previously noted, because CO is infrequently measured in PICUs, SVR is most commonly inferred from observation of cutaneous perfusion and SAP. Indeed, it is important to evaluate systemic hypotension in the context of cutaneous perfusion (brisk capillary refill suggests low SVR) because rational therapy for decreased SVR with adequate CO (vasopressor support) is quite different from that useful for hypotension due to inadequate CO.

Increased Pulmonary Vascular Resistance

The clinical consequences of increased PVR are directly related to the specific cardiac anatomy and physiology. With two separate ventricles, high PVR can reduce systolic and diastolic function of the pulmonary ventricle and limit its output. In patients with a physiologically large aortopulmonary shunt, increased PVR, up to a point, can be useful because it reduces what would otherwise be excessive PBF. On the other hand, if PVR is too high, or in the setting of an excessively restrictive aortopulmonary shunt, inadequate PBF results. With a bidirectional Glenn circulation, elevated PVR may result in upper body congestion and hypoxemia. With a Fontan circulation, high systemic venous pressure, low CO, and hypoxemia (if a fenestration is present) may occur.

In patients with a structurally normal cardiovascular system, measuring PVR is analogous to measurement of SVR and is subject to the same practical difficulties. Echocardiographic estimation of RV pressure is a useful surrogate, using a tricuspid regurgitant jet, pulmonary regurgitant jet, or interventricular septal position. Unfortunately, in the absence of significant tricuspid regurgitation (or another defect that allows a pressure gradient to be measured between the right ventricle and a chamber of known pressure), echocardiographic estimation of RV pressure is crude.

For patients with an aortopulmonary shunt, PVR is rarely measured in the ICU; determining PBF requires measuring VO_2 (an assumed VO_2 is questionable because it is so variable[9]), pulmonary arterial O_2 saturation, and pulmonary venous O_2 saturation. Because pulmonary venous catheters are rarely used, pulmonary venous O_2 saturations are usually assumed; however, this is a potential source of significant error because these saturations are variable and unpredictable.[36] Most important, pulmonary artery pressure is essentially never measured in the critical care unit in patients with shunts. For these patients, even estimating PVR is problematic because many variables (eg, PVR, systemic blood pressure, PBF and CO, hematocrit, and VO_2) influence the most obvious manifestation of increased PVR, low systemic arterial O_2 saturation. Circumstantial data may be used to infer that PVR is not elevated in hypoxemic patients with an aortopulmonary shunt; for example, echocardiographic demonstration of narrowing of the shunt suggests that increased PVR is likely not the cause of the hypoxemia. Alternatively, an increase in systemic arterial O_2 saturation with inhaled nitric oxide would also suggest that baseline PVR is increased.

Measuring PBF in patients with a cavopulmonary palliation (eg, bidirectional Glenn, hemi-Fontan, and Fontan) can also be done using the Fick method (thermodilution cannot be used to measure PBF because of inadequate mixing of the cold indicator in the systemic venous pathway). From a practical standpoint, increased PVR in this setting is often inferred from high systemic venous pathway pressures (superior vena caval pressures in a bidirectional Glenn patient), taking into consideration possible anatomic obstruction in the superior vena cava, pulmonary arteries, or pulmonary veins or increased systemic ventricular end-diastolic pressures.

Inefficient Circulation

The most important fundamental ways that structural defects can result in an

inefficient circulation in patients with cardiac structural lesions are (1) increased ventricular afterload (eg, RV or LV outflow tract obstruction), (2) increased ventricular volume load (eg, ventricular septal defect and atrioventricular valve regurgitation), (3) impaired ventricular filling (eg, atrioventricular valve stenosis), (4) reduced PBF with shunting into the systemic circulation, (5) mixing of pulmonary and systemic venous blood, and (6) D-transposition of the great arteries physiology (ie, PVR predominantly directed to the PA and SVR predominantly directed to the aorta). Impaired coronary perfusion resulting in ventricular ischemia is perhaps not, conceptually, a problem of efficiency but a structural lesion that needs to be considered. Many patients have some combination of these lesions. It is beyond the scope of this chapter to discuss the evaluation of cardiac patients relative to structural lesions and their impact on DO_2, systemic perfusion pressure, and QOT. Suffice it to say that it is exceedingly important that the anatomy and associated physiology of patients with cardiac malformations be well defined. Echocardiography is the single most useful modality for delineating cardiac structure (and often even physiology) in the critical care unit. Cardiac catheterization and angiography remain important diagnostic and therapeutic tools, and MRI and CT are sometimes helpful.

Vascular Integrity

By vascular integrity we refer to the ability of the vascular (mostly microvascular) bed to keep fluid in the intravascular space. Leaky blood vessels result in organ, chest wall, and peripheral edema, as well as fluid accumulation in the thoracic and abdominal cavities. This situation is exacerbated by high CVP, particularly when ventricular diastolic dysfunction exists, and tends to be self-perpetuating, especially in infants (Fig. 29.1).

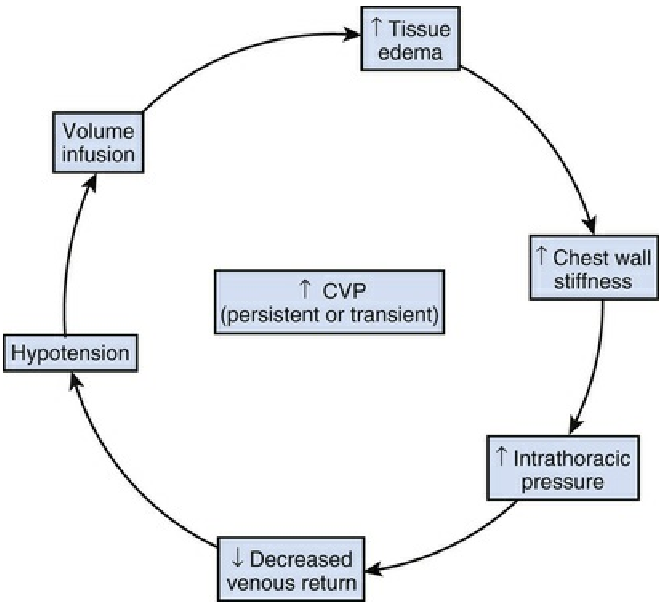

FIG. 29.1 Flow diagram.

It is important to assess third spacing, particularly in infants, where opening the

chest may help minimize the hemodynamic effects of chest wall edema in post–cardiac surgical patients. Similarly, assessment for abdominal compartment syndrome due to ascites may allow surgical or catheter-based evacuation with improved pulmonary mechanics and urine output. Also, because progressive edema, even if relatively benign early on, is likely to eventually become a significant problem, this finding should figure prominently in the clinician's overall assessment of the patient's condition.

Pulmonary Function

Pulmonary dysfunction due to edema or acute or chronic lung injury can be a major physiologic liability for the obvious reasons related to impaired gas exchange. In addition, insofar as increased P_{aw} is required for adequate gas exchange, venous return to the heart may be impaired. This can be especially important in special circumstances, such as the patient after cavopulmonary palliation. Williams and colleagues[37] nicely showed the unfavorable impact of small increments of positive end-expiratory pressure in patients after Fontan palliation, which, as careful inspection of their data reveals, was mostly due to decreased venous return. Increased P_{aw}, especially if it causes overinflation of the lungs, also can increase PVR. Finally, increased P_{aw}, if applied for sufficient duration, can take a long-term toll by chronic reduction in lung function.

It is beyond the scope of this chapter to describe all available techniques for evaluating lung function. However, high P_{aw} is an important component of QOT and should lead the intensivist to consider alternatives (eg, permissive hypercapnia or extracorporeal life support).

Physiology of the Patient with a Single Ventricle

Patients with single-ventricle physiology differ from children with two functioning ventricles in many ways. They pose several unique challenges to the pediatric intensivist. For many patients with a single ventricle, initial palliation in infancy may involve placement of an aortopulmonary (eg, modified Blalock-Taussig) or right ventricle to PA (“Sano”) connection as a source of PBF. The total output of the single-ventricle circulation is thus the sum of the pulmonary (Q_p) and systemic (Q_s) blood flows. The relative percentage of blood flow to the pulmonary and systemic circulations depends, in part, on the resistance in each vascular bed. Because PVR is usually substantially lower than SVR soon after birth, the size (diameter, length, and vessel of origin) of the aortopulmonary shunt is also a major contributor to total resistance to flow in the pulmonary circuit and hence an important determinant of Q_p/Q_s. SVR is often the single most important variable influencing Q_p[38] and the one most amenable to manipulation in the ICU. In patients with a single ventricle who have complete admixture of systemic and pulmonary venous blood, arterial O_2 saturation is influenced by not only lung function (eg, pulmonary venous O_2 saturation) but also Q_p and myocardial function (which influences Q_s and, hence, mixed venous O_2 saturation) (Figs. 29.2 and 29.3).

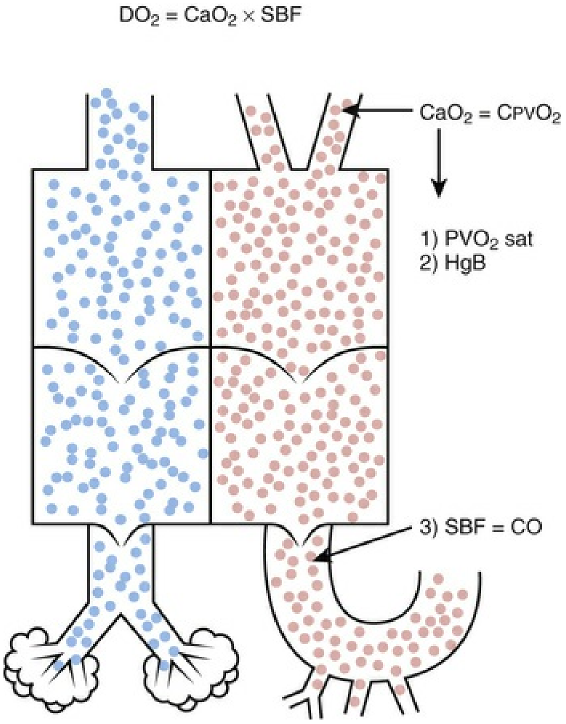

FIG. 29.2 Cartoon depicting the variables that determine systemic oxygen delivery (DO_2) with a normal heart. Blue dots depict desaturated (systemic venous) blood, and red dots depict fully saturated (pulmonary venous) blood. *CaO_2,* systemic arterial blood O_2 content; *CO,* cardiac output; *$CpVO_2$,* pulmonary venous blood O_2 content; *HgB,* blood hemoglobin concentration; *PvO_2 sat,* pulmonary venous O_2 saturation; *SBF,* systemic blood flow. Dissolved O_2 in the blood is ignored.

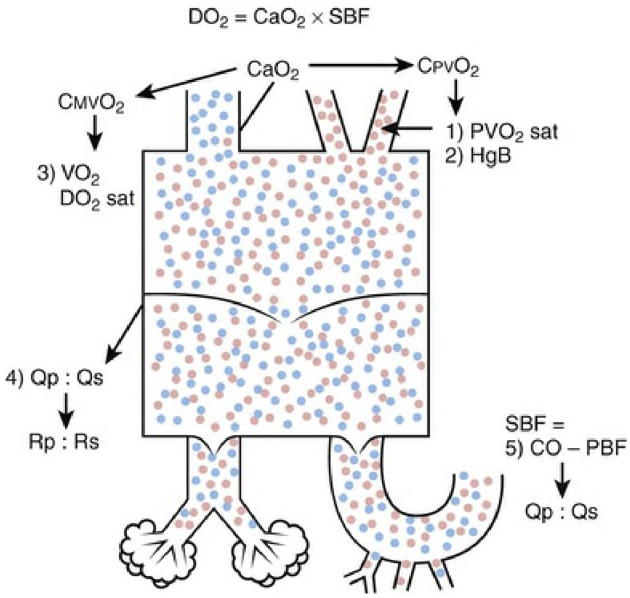

FIG. 29.3 Cartoon depicting the variables that determine systemic oxygen delivery (DO_2) with a cardiac malformation resulting in complete mixing of systemic and pulmonary venous blood. Blue dots depict desaturated (systemic venous) blood, and red dots depict fully saturated (pulmonary venous) blood. *CaO_2,* systemic arterial blood O_2 content; *$CMvO_2$,*

systemic venous O_2 content; *CO,* cardiac output; *$CpVO_2$,* pulmonary venous blood O_2 content; *HgB,* blood hemoglobin concentration; *PvO_2 sat,* pulmonary venous O_2 saturation; *PBF,* pulmonary blood flow; *Qp : Qs,* ratio of pulmonary to systemic blood flow; *Rp : Rs,* ratio of pulmonary to systemic vascular resistance; *SBF,* systemic blood flow; *VO_2,* total body O_2 consumption. Dissolved O_2 in the blood is ignored.

Computer modeling of shunt-dependent single-ventricle physiology[31] suggests that a Q_p/Q_s ~ 1.0 is ideal for optimizing systemic O_2 availability for a given pulmonary venous O_2 saturation, CO, and VO_2. The arterial O_2 saturation, considered in isolation, is a poor indicator of Q_p/Q_s because a low mixed venous O_2 saturation will depress arterial O_2 saturation, even in patients with a high Q_p/Q_s. Accurately measuring Q_p/Q_s, which equals systemic arterial O_2 saturation minus systemic venous O_2 saturation divided by pulmonary venous O_2 saturation minus pulmonary arterial O_2 saturation, requires determining O_2 saturation in blood in the proximal superior vena cava (SVC), as distinct from RA or inferior vena cava, and is subject to the previously noted variability and unpredictability of pulmonary venous O_2 saturations. That said, estimating Q_p/Q_s using the SVC O_2 saturation (as mixed venous) and the arterial O_2 saturation (which is also the PAO_2 saturation) and assuming the pulmonary venous O_2 saturation is helpful in estimating whether a patient with a single ventricle and an aortopulmonary shunt has appropriate (ie, associated with optimal systemic DO_2), increased, or decreased Q_p/Q_s. However, it is important to note that Q_p/Q_s is merely a number when considered in isolation. It must be placed into the context of the patient's overall status, considering the parameters previously outlined for assessing systemic DO_2. In particular, in patients following single-ventricle palliation, a progressive decline in the serum lactate concentration (regardless of the initial postoperative concentration) is a fairly sensitive and specific marker for early survival. In contrast, rising lactate levels are generally a robust predictor of early postoperative cardiovascular collapse or need for mechanical support unless therapy can improve the hemodynamic picture.[15]

It should be noted that the physiology is somewhat different in patients with two ventricles and an aortopulmonary shunt (eg, tetralogy of Fallot with severe RV outflow tract obstruction and a modified Blalock-Taussig shunt). Because PBF is usually made up of both systemic arterial blood and systemic venous blood, arterial O_2 saturation is higher for a given amount of PBF and cannot be calculated using systemic arterial O_2 saturation as the PAO_2 saturation.

Although the cardiopulmonary physiology of patients with bidirectional Glenn palliation differs somewhat from that of others (eg, the apparent paradoxical relationship between alveolar ventilation and arterial O_2 saturation[39,40]), cardiovascular assessment is much the same as for other patients. Two things are worth noting, however. First, because arterial O_2 saturations often increase significantly during the first several postoperative hours after Glenn palliation, lower than desired but acceptable O_2 saturations early on do not necessarily imply inadequate palliation. Second, although some degree of upper body edema and duskiness is not unusual soon after an operation, marked upper body congestion

suggests the possibility of obstruction of the SVC to PA pathway, which requires prompt evaluation. Echocardiography may be sufficient to interrogate this pathway, although angiography may be required.

Evaluation of postoperative Fontan patients is also much the same as for other postoperative cardiac patients, but because Fontan patients are particularly sensitive to factors that impede transit of blood across the lungs and into the ventricle, it is important to identify any such factors, especially remediable ones, early on in the struggling patient. Anatomic abnormalities that might have little clinical importance in other circumstances (eg, partial obstruction of one or more pulmonary veins) can have a marked impact on the early postoperative Fontan patient. The same goes for modestly increased PVR and mildly decreased ventricular compliance. Catheters in the central systemic veins and left atrium are useful for estimating PVR and ventricular compliance, and the previously noted measures of systemic perfusion are helpful. The sick postoperative Fontan patient may pose the perfect storm of marginal SAP, acutely elevated CVP (relative to preoperative CVP), and hypoxemia (from right-to-left shunting of highly desaturated systemic venous blood through a fenestration), all complicated by the use of inotropic agents (which increase myocardial and total body VO_2). The experienced intensivist will consider these multiple variables, including the QOT, in aggregate when evaluating the patient.

CHAPTER 30

Myocardial Dysfunction, Extracorporeal Life Support, and Ventricular Assist Devices

Ana Lía Graciano, Umesh Joashi, Keith C. Kocis

PEARLS

- Advances in medical management, surgical techniques, and mechanical circulatory support for pediatric patients with congestive heart failure continue to improve patient outcomes.
- Indications for use of mechanical circulatory support continue to evolve.
- Patient size, expected duration of support, and goals of support (ie, bridge to recovery versus bridge to transplant) must be considered in the choice of a mechanical circulatory support device.
- Mechanical circulatory support is a lifesaving therapeutic option for patients with advanced heart failure. Device options in children are expanding but remain limited due to their size constraints.
- In children, most short-term mechanical circulatory support continues to be achieved with extracorporeal life support.
- Small patients (<6 kg), renal failure, and the need for biventricular support greatly increase the risk of death during support.
- A multidisciplinary team approach to the selection of the appropriate mechanical circulatory device is critical to a successful outcome.

Introduction

Mechanical circulatory support (MCS) is an invaluable tool in the care of children with severe refractory cardiac or respiratory failure. Two forms of mechanical support are currently available to infants and small children; these include

extracorporeal life support (ECLS) and ventricular assist devices (VADs). Patient selection, timing of intervention, and device choice continue to pose a challenge in the treatment of pediatric patients.

This chapter reviews the basics of myocardial dysfunction in children with an emphasis on low cardiac output syndrome and its treatment with regard to mechanical circulatory support. Finally, we outline indications for MCS, salient technical details of specific devices, patient management, present research, and future directions of these technologies for use in pediatric patients.

Pediatric Heart Failure

Heart failure (HF) is the final pathway of many pathophysiologic states affecting cardiovascular performance leading to inadequate cardiac output and decreased end-organ perfusion with diminished oxygen delivery to the vital organs. These include states of altered preload, afterload, contractility, and abnormal heart rate or rhythm. The etiology of the different types of heart failure in children is listed in Table 30.1,[1] with the largest disease burden being due to congenital malformations and cardiomyopathies.[2,3]

TABLE 30.1
Etiology of Heart Failure in Children

Congenital Cardiac Malformations
Volume Overload
Left-to-Right Shunting
Ventricular septal defect
Patent ductus arteriosus

Hsu DT, Pearson GD. Heart failure in children: part I: history, etiology, and pathophysiology. Circ Heart Fail. 2009;2:63-70.

The primary goal in the management of myocardial dysfunction is to ensure adequate tissue oxygen delivery, as an imbalance between delivery and consumption results in organ dysfunction and failure. Initial therapies to treat decompensated heart failure target providing respiratory support; decreasing metabolic demands (ie, work of breathing); optimizing preload, afterload, and contractility; and optimizing heart rate and rhythm. Despite advances in pharmacologic therapies (eg, nesiritide, levosimendan, milrinone, amiodarone) a group of patients will continue to deteriorate or require excessive cardiopulmonary support. This group should be evaluated early for MCS before additional end-organ dysfunction or irreversible damage occurs. Several innovative types of MCS are being created and brought into clinical care while extended indications, management strategies, and outcomes are currently being developed. Simultaneously, ECLS continues to improve and remain the most commonly deployed form of MCS for infants and children.[4,5]

Low Cardiac Output Syndrome

Low cardiac output syndrome (LCOS) describes a clinical state with specific biochemical markers where there is inadequate systemic oxygen delivery (DO_2) to meet the metabolic demand (VO_2) of the patient. The condition has been recognized since the 1960s, and multiple studies have documented the predicted changes in physiologic parameters. LCOS has been an active area of research, and multiple reviews of current therapies are available to guide the intensivist.[6] LCOS is frequently seen in severe sepsis, myocarditis, cardiomyopathies, and after pediatric cardiac surgery. Postoperative physiologic changes secondary to cardiopulmonary bypass, myocardial ischemia during aortic cross clamping, cardioplegia, residual lesions, ventriculotomy, changes in the loading conditions to the myocardium, and dysrhythmias may all contribute to the development of LCOS. A variety of proinflammatory triggers are activated during cardiopulmonary bypass as a result of blood contact with foreign surfaces, ischemia, reperfusion, tissue trauma, and temperature changes. This complex inflammatory response includes complement activation, cytokine release, leukocyte and platelet activation, and the expression of adhesion molecules. LCOS has been reported to affect up to 25% of infants and children, typically occurs between 6 and 18 hours after cardiac surgery, and results in a longer intensive care stay and increased mortality. It is associated with elevated systemic and pulmonary vascular resistances, impaired myocardial function, and

dysrhythmias. When unrecognized or inadequately treated, LCOS can result in irreversible end-organ failure, cardiac arrest, and death. Prevention, early recognition, and optimal treatment are essential to ameliorate or reverse its course.[7]

Definitions

Achieving a balance between O_2 supply and demand is essential and can be accomplished by decreasing oxygen consumption (VO_2) or increasing oxygen delivery (DO_2). VO_2 is determined by tissue metabolism and is increased during periods of increased muscular activity (ie, seizures, exercise), infection, fever, or with increased levels of circulating catecholamines. Normally the ratio between DO_2 and VO_2 is 5 : 1 and when VO_2 increases according to increased metabolic demands, DO_2 adjusts accordingly. When the rate of oxygen consumption exceeds DO_2, anaerobic metabolism begins. Systemic oxygen delivery (DO_2) is defined as the amount of O_2 delivered to peripheral tissues each minute and is determined by cardiac output and the oxygen content of arterial blood as shown by the Fick equation that follows, where DO_2 refers to oxygen delivery and CO refers to cardiac output. Arterial oxygen content (CaO_2) is determined by hemoglobin (Hb) concentration, the arterial oxygen saturation (SaO_2), and the partial pressure of oxygen in the arterial blood (PaO_2). Cardiac output (CO) is defined as the product of heart rate (HR) × stroke volume (SV):

$$VO_2 = CO\ (CaO_2 - CvO_2)$$

$$DO_2 = CO \times CaO_2$$

$$CaO_2 = (Hb \times 1.36 \times SaO_2) + (PaO_2 \times 0.003)$$

$$CO = HR \times SV$$

Predictable changes in cardiac output have been demonstrated in newborns following the arterial switch operation for transposition of the great vessels. The median maximal decrease in cardiac index (32%) occurred approximately 6 to 12 hours after separation from cardiopulmonary bypass and nearly a quarter of these newborns reached a nadir of cardiac index that was <2 L/min/m^2.[8] The fall in cardiac index was coupled with a rise in the calculated systemic and pulmonary vascular resistance. Intraoperative perfusion strategy with either low-flow bypass or circulatory arrest was not associated with postoperative hemodynamic status or other postoperative events other than neurologic adverse events, which were higher with the use of deep hypothermic circulatory arrest (DHCA).[8]

Assessment

Although a complete assessment of oxygen delivery and consumption in critically ill infants and children is extremely challenging, numerous hemodynamic and biochemical parameters can be readily obtained to help guide the bedside clinician. Mixed venous oxygen saturation (SvO_2) or central venous oxygen saturation ($ScvO_2$), arterial lactate, and near-infrared spectroscopy (NIRS) are important biomarkers that can be serially measured in patients at risk for LCOS. SvO_2 and $ScvO_2$ are a reflection of the total body DO_2/VO_2 ratio and can be important metrics to follow in critically ill patients.[9,10] An elevated lactate level on admission (>4.5 mmol/L) and rising at 0.9 mmol/L/hr postoperatively is associated with major adverse events including death in infants after cardiac surgery.[11] Furthermore, lower SvO_2 may increase the predictive power of elevated arterial lactate levels for mortality after pediatric cardiac surgery.[6,12]

It is not uncommon to observe a disparity between direct measurements of DO_2 and cardiac output and estimates based on physical examination and interpretation of conventional laboratory and hemodynamic parameters.[7,13,14] Compensatory increases in systemic vascular resistance maintain arterial blood pressure as cardiac output decreases and central venous pressures may not correlate well with ventricular filling.[8,15] Femoral venous catheters are routinely placed in neonates and children, including an additional factor (intraabdominal pressure) in the accurate interpretation of these continuous variables. The effects of positive pressure ventilation on these measurements are well described.[16] Hemodynamic stability in the early postoperative period after the Norwood palliation depends on an adequate cardiac output and a balanced pulmonary-to-systemic blood flow ratio (Qp : Qs). The systemic oxygen saturation (SaO_2) alone is a poor predictor of Qp : Qs because of variability in systemic venous oxygen saturation (SvO_2) and pulmonary vein saturation ($SpVO_2$) after the Norwood operation. Monitoring and optimizing SvO_2 have been shown to improve outcomes in pediatric patients at risk for developing shock, including hypoplastic left heart syndrome.[9,17,18] Intermittent SvO_2 monitoring can be obtained to assess oxygen transport balance, but the presence of intracardiac shunts near the site of sampling and the need for repeated blood sampling limits its universal use. It has been reported that when SvO_2 monitoring is used in the postoperative care of critically ill neonates, significantly fewer adverse events are encountered, particularly with SvO_2 greater than 50%. Significant decreases in SvO_2 can occur without appreciable changes in arterial oxygen saturation, blood pressure, or heart rate. When low SvO_2 is recognized, increased inodilator support and measures that decrease metabolic demands (ie, sedation, neuromuscular blockade) often successfully return this metric to the normal range. In contrast, ventilator and inspired gas adjustments have less effect on SvO_2. The critical oxygen extraction ratio is defined by the onset of shock and ranges from 50% to 60%.[11,19,20] The critical DO_2 changes in parallel with changes in oxygen consumption even though the critical oxygen extraction ratio remains constant. When the critical oxygen extraction ratio is exceeded, SvO_2 decreases. This is an important consideration postoperatively when oxygen demand changes over time and with therapy.

Cerebral NIRS noninvasively assesses cerebral tissue oxygenation and relies on the relative lucency of biological tissue to near-infrared light where oxy- and

deoxyhemoglobin have distinct absorption spectra,[18,21,22] and the oximeter monitors the nonpulsatile signal reflecting the microcirculation where 75% to 85% of the blood volume is venous. Thus the NIRS-derived oxygen saturation is an indicator of oxygen extraction for the region of brain beneath the optode. There is a good correlation between cerebral oxygen saturations, jugular bulb, and superior vena cava (SVC) saturations.[23,24] Cerebral oxygen saturations are closely and negatively correlated with the oxygen extraction ratio in neonates following the Norwood procedure. Strategies measuring regional venous weighted oxygen saturation in both cerebral and somatic regions provide better estimates of SvO_2 and a stronger relationship to outcome.

The pulse contour cardiac output (PiCCO) measurement system allows continuous hemodynamic monitoring using a large (femoral, brachial, or axillary) artery catheter and a central venous catheter. This technology uses intermittent transpulmonary thermodilution and pulse contour analysis. With the use of specific algorithms, various parameters such as cardiac output, extravascular lung water (EVLW), global end-diastolic volume (GEDV), pulse pressure variation (PPV), and stroke volume variation (SVV) can be obtained. PiCCO can assist in preload assessment in a volumetric manner. In patients with septic shock, GEDV calculated by PiCCO was found to be a better index of cardiac preload when compared with CVP in a prospective clinical study. The PiCCO may give inaccurate measurements in patients with arrhythmias, rapid temperature changes, intra/extracardiac shunts, aortic aneurysm, aortic stenosis, pneumonectomy, pulmonary embolism, and extracorporeal circulation.[19,25] The USCOM ultrasonic cardiac output monitor (USCOM Pty Ltd, Coffs Harbour, NSW, Australia) is a noninvasive device that determines cardiac output by continuous-wave Doppler ultrasound but pediatric data are limited.[26,27]

Specific Treatments to Improve Cardiac Function

In contrast to adult patients, tremendous heterogeneity exists between the etiology and pathophysiology of heart failure in pediatric patients. Despite these differences, treatment strategies for pediatric patients have followed the recommendations from large, randomized, multicenter trials in adult patients or "consensus" opinions based on single "best" institution clinical practices due to a lack of randomized, multicenter, pediatric clinical trials. With the expanded authority and mandates of the Food and Drug Administration (FDA) Pediatric Advisory Committee and the origins of the National Institutes of Health (NIH) Collaborative Pediatric Critical Care Research Network (CPCCRN) and the new Pediatric Cardiac Critical Care Consortium (PC4), the future is brighter for high-quality clinical trials in children.[28]

Outpatient management of chronic congestive heart failure with digitalis formed the basis of early therapy (~1970s) despite its narrow therapeutic index for safety. Loop or thiazide diuretics with the addition of the potassium-sparing antimineralocorticoid, spironolactone, were also commonly used, although drug compounding for children and potassium monitoring was problematic. Angiotensin-converting enzyme inhibitors (ACE-I) exert favorable effects on cardiac remodeling and survival in adults with congestive heart failure although their role in children is less clear, as a randomized, placebo-controlled trial in children evaluating the effect of ACE-I in single ventricle patients failed to demonstrate a beneficial effect.[29,30]

The nonselective β-blocker, propranolol, has been commonly used in pediatric cardiology for the treatment of dysrhythmias despite the need for frequent dosing. Selective β-blockers, like metoprolol, are a mainstay in adult cardiac patients with some use in children.[31,32] The nonselective β-blocker/α_1-blocker, carvedilol, has increased use in pediatric heart failure treatment. Most pediatric uses of these drugs have been extrapolated from the positive effects seen in adult trials that demonstrated a reduction in mortality and risk of hospitalization. Single-center trials have demonstrated both improved ejection fraction with the use of carvedilol in children awaiting heart transplantation with dilated cardiomyopathy and a delayed time to transplantation or death.[33] However, the most recent and largest multicenter, randomized, double-blind, placebo-controlled controlled trial of carvedilol in children and teenagers with symptomatic systolic heart failure did not demonstrate an improved survival benefit.[34]

For hospitalized children, LCOS has been traditionally managed using continuous infusions of catecholamines or their analogs (ie, dopamine, epinephrine, and dobutamine) to increase cardiac contractility (β_1) while avoiding tachycardia (β_1) and increases in systemic (SVR) or pulmonary vascular resistance (PVR) (α_1). Norepinephrine with its potent α_1 effects and lack of β_2 (vasodilatory) effects is generally not utilized unless a low SVR state is present (ie, septic shock). However, these agents when used in high doses can be deleterious on global and myocardial VO_2, induce myocardial cell apoptosis, and lead to increased mortality.

Milrinone, a phospodiesterase-3 inhibitor, has emerged as an important *inodilating* agent, which is now widely used in children after open-heart surgery after a landmark study showed that the prophylactic use of milrinone was associated with a decreased likelihood of LCOS in children after open-heart surgery in a dose-dependent fashion.[35] This benefit is thought to result from both improved myocardial contractility as well as pulmonary and systemic vasodilatory effects. Milrinone reduces right and left ventricular afterload through systemic and pulmonary vasodilatation and improves diastolic relaxation (lusitropy) of the myocardium through its enhanced cAMP-dependent diastolic reuptake of calcium.[36]

Sildenafil, an IV or oral drug that inhibits cGMP-specific phosphodiesterase type 5 (PDE5) causing smooth muscle relaxation, has proved to be beneficial in neonates with severe pulmonary hypertension and as an adjunct in weaning these patients from inhaled nitric oxide.[37,38]

Levosimendan, a relatively new drug, is a calcium sensitizer that enhances the contractility of the ventricle by binding to cardiac troponin C. In addition, the drug acts as a vasodilator by opening ATP-sensitive potassium channels in the vascular smooth muscle resulting in decreases in SVR and PVR. The improvement in myocardial performance is accomplished without an increase in intracellular calcium, thus providing a cardioprotective effect. Finally, an active metabolite with a half-life of ~3 days prolongs the duration of action for this continuously infused medication.[39]

Broad Treatment Strategies

Supportive care for decompensated heart failure begins with strategies aimed at improving the specific components of DO_2 and VO_2 listed previously (Fig. 30.1). This

includes standard critical care therapies primarily focused on noncardiac support, such as intubation and mechanical support for respiratory insufficiency; temperature control, red cell transfusion for significant anemia; and control of pain and agitation with analgesia and anxiolysis. Mechanical respiratory support decreases metabolic demands by decreasing the work of breathing, reduces left ventricular afterload (wall stress), and can improve arterial oxygen saturation (SaO_2) by the administration of oxygen and PEEP, thus increasing CaO_2. However, endotracheal intubation can be risky in decompensated patients with HF, as the induction agents, laryngoscopy, and conversion to positive pressure ventilation can induce cardiac arrest. The benefits of noninvasive positive pressure ventilation (facial BiPAP) have not been proved and the risks remain significant, particularly with regard to delay in timing for intubation and the need for additional sedation in children.

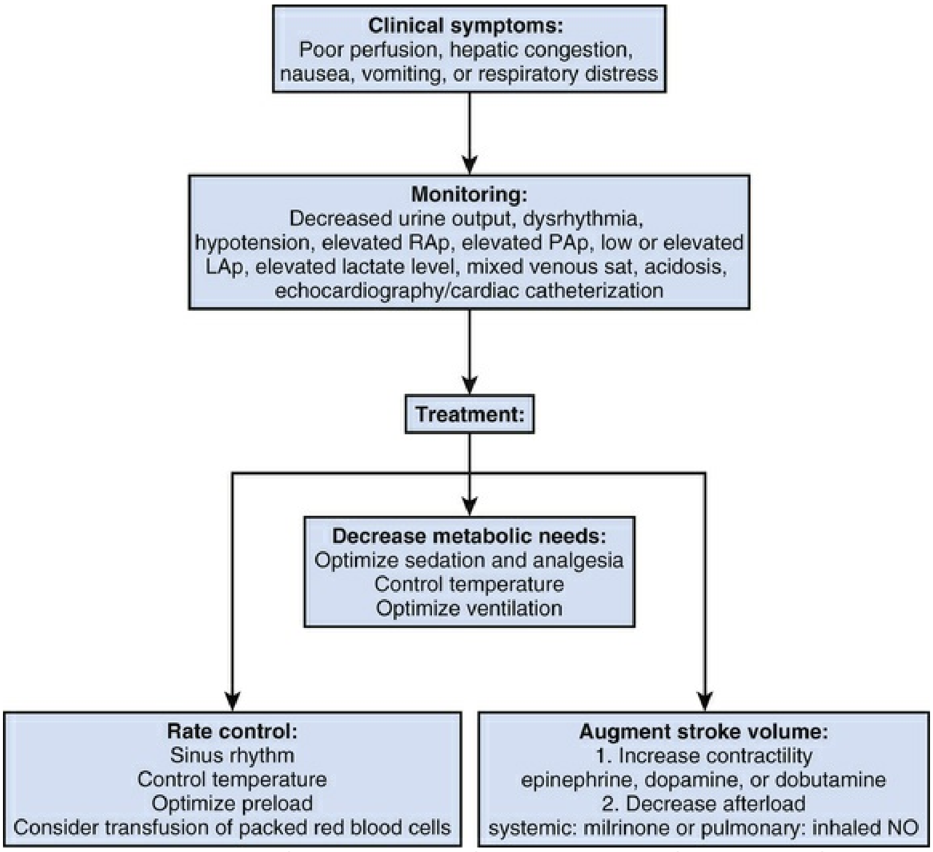

FIG. 30.1 Algorithm for treatment of ventricular dysfunction. *NO*, nitric oxide.

CaO_2 can also be increased by transfusing packed red blood cells (PRBCs) to increase hemoglobin concentrations in significant anemia. Research has not demonstrated a negative impact on patient outcomes when a restrictive transfusion practice was embraced, though the study did not examine complex or high-risk congenital cardiac patients or those with unrepaired or palliated cyanotic cardiac defects where a relative polycythemia is normally maintained to compensate for the decrease in SaO_2. Clearly, numerous, significant, deleterious effects on the recipient occur after allogenic blood transfusion, and the risk of donor-directed blood can be

greater. In patients who are euvolemic, avoidance of hypervolemia with worsening pulmonary edema must be prevented when the decision to transfuse red cells is made.

Cardiopulmonary bypass results in numerous significant neurohormonal perturbations in the neonate after cardiac surgery. In particular, critical illness-related corticosteroid insufficiency and disruption of normal thyroid axis function can occur. Several studies have demonstrated acute salutary effects of postoperative therapy with both hydrocortisone and triiodothyronine without significant adverse effects,[40] although better clinical outcomes beyond the immediate hemodynamic improvements have yet to be shown. Adult patients who undergo open-heart surgery and receive triiodothyronine (T3) supplementation have demonstrated a dose-dependent increase in cardiac output, which has been associated with an improved clinical outcome. In multiple small studies in neonates and children after cardiopulmonary bypass, the serum thyroid panel identifies a pattern of sick euthyroid syndrome. Supplementation with T3 has variably led to increases in specific hemodynamic parameters, improved diuresis, and a decreased need for additional cardiopulmonary support. Regardless, a 2007 systematic review concluded that there is lack of evidence that T3 supplementation is beneficial in the prevention of morbidity and mortality in children undergoing cardiac surgery.[41]

Terlipressin is a synthetic long-acting analog of vasopressin, with a higher affinity for vascular V_1 receptors than vasopressin. Terlipressin has been used in adult patients to treat extremely low cardiac output, but its application in children is limited. In postoperative pediatric cardiac patients, terlipressin demonstrated an improvement in respiratory, hemodynamic, and renal indices in refractory low cardiac output syndrome.[42] Although these results are encouraging, further investigation with prospective randomized trials is needed to provide data regarding the efficacy and safety of terlipressin in infants and children.

Inhaled nitric oxide (iNO) is a potent short-acting vasodilator resulting in numerous beneficial cardiopulmonary effects on the pulmonary, systemic, and coronary circulations. Its use is standard for severe, reversible pulmonary hypertension in the neonate and in children with congenital heart disease. It is also useful in the treatment of right ventricular failure. A variety of other drugs (eg, nitroprusside) and amino acids (arginine, citrulline) are precursors to NO and thus increase its circulating levels. Another beneficial effect of NO is the inhibition of platelet function and aggregation, which can complicate a variety of cardiovascular diseases in children.[43]

Fenoldopam, a selective dopamine-1 receptor partial agonist, causes systemic vasodilatation and increased renal blood flow with improved renal function in adults. Two meta-analyses have concluded that fenoldopam use in critically ill adult patients at risk of acute kidney injury decreases the development of acute tubular necrosis, requirement for renal replacement therapy, length of ICU stay, and overall patient mortality. One study also demonstrated a reduction in the time on mechanical ventilation.[44] Data on the use of fenoldopam in pediatric patients are sparse, with one retrospective study demonstrating a significant improvement in diuresis in neonates after cardiopulmonary bypass with the addition of fenoldopam to conventional diuretic therapy, whereas another prospective trial failed to demonstrate a beneficial effect.[45]

Mechanical Circulatory Support in Pediatric Patients

Brief Historical Perspective

Since 1953 when John Gibbon first utilized extracorporeal perfusion in the operating room, the indications and utilization of MCS have continued to expand. Technologic advances have afforded support for thousands of patients per year with a variety of respiratory or cardiac indications. Early trials of extracorporeal membrane oxygenation (ECMO) were marked by mixed results. In 1985 Bartlett and colleagues reported the first successful use of ECMO in a newborn.[46] Since then, neonates with diagnoses of meconium aspiration syndrome, persistent pulmonary hypertension, and congenital diaphragmatic hernia have been treated for severe respiratory failure unresponsive to conventional therapies. ECMO for cardiac support was first used in the 1970s, but it was not until the 1990s that it became a common therapeutic technique for myocardial failure. As of January 2015, a total of 65,171 pediatric and neonatal patients were registered within the Extracorporeal Life Support Registry (ECLS Registry Report International Summary January 2015) (Table 30.2). VADs have been successfully used in adults since the early 1970s. The favorable results seen in the adult prompted the adaptation of the adult technology for pediatric patients. Worldwide experience with VADs to support the neonates and infants as a bridge to either recovery or transplantation continues to grow.

TABLE 30.2

Extracorporeal Life Support Organization Registry Outcomes as of July 2015

ECPR, extracorporeal cardiopulmonary resuscitation.

Acute decompensated heart failure is a critical condition that requires prompt and aggressive intervention and, when medical treatment is maximized or ineffective, patients should be considered for MCS for either temporary support until heart function recovers, as a bridge to heart transplantation, or as a destination therapy (ie, life with permanent MCS). MCS through a variety of devices can support right, left, or biventricular failure. This is accomplished with devices that are either extracorporeal (outside the human body), paracorporeal (partial within and outside the human body), or intracorporeal or implantable (residing completely within the human body). MCS devices can provide either pulsatile flow or continuous flow depending on the specific design. MCS can also be provided to the left ventricle

alone with an intraaortic balloon pump or it can replace the entire function of the heart with a totally artificial heart. Finally, cardiac and pulmonary support can be provided with the addition of a membrane oxygenator to specific types of extracorporeal circulatory devices (ECLS). Venoarterial ECLS provides cardiopulmonary support, whereas venovenous ECLS provides only pulmonary support for severe respiratory failure.

Despite improvements in operative techniques, management of cardiopulmonary bypass, and myocardial protection, myocardial dysfunction and failure can occur after surgery for congenital heart disease with involvement of the left or right ventricles. Approximately 5% of children undergoing cardiac surgery require MCS. The patient's underlying pathophysiology, size, and expected length of support dictate which technique is most suitable. In children, most mechanical circulatory support continues to be achieved with ECLS. Since ECLS and VADs have advantages and disadvantages, determining the most appropriate modality for the individual patient requires significant expertise.

Extracorporeal Life Support

ECLS is the most utilized form of short-term MCS support for pediatric patients with decompensated heart failure unresponsive to medical therapy. Adaptations and simplification of the traditional cardiopulmonary bypass circuit have resulted in the standard venoarterial ECLS circuit (Fig. 30.2) through either extrathoracic (ie, carotid artery/jugular vein or femoral vessels) or transthoracic (right atrium/ascending aorta) placement after median sternotomy. The venous cannula allows for passive drainage of blood from the patient into a bladder, which then passes through a servo-regulated roller-head or centrifugal pump that propels blood through the remainder of the system at high pressure. Gas exchange (O_2 addition and CO_2 removal) occurs next through an artificial lung (oxygenator, comprising a silicone membrane or hollow fibers) where countercurrent sweep gas passes external to the blood phase. Blood temperature is controlled by a heat exchanger. Finally, blood is returned to the body into a major artery. Additional components include ports on the venous side (preoxygenator) for infusion of medications, pressure and flow monitors, oxygen saturation or blood gas analyzers for both the venous and arterial blood, bubble detectors, placement of a hemofilter for fluid control or dialysis (venovenous or arteriovenous), and, frequently, a bridge connecting the venous and arterial sides of the circuit for use during trials off ECLS or in case of a circuit emergency.[47]

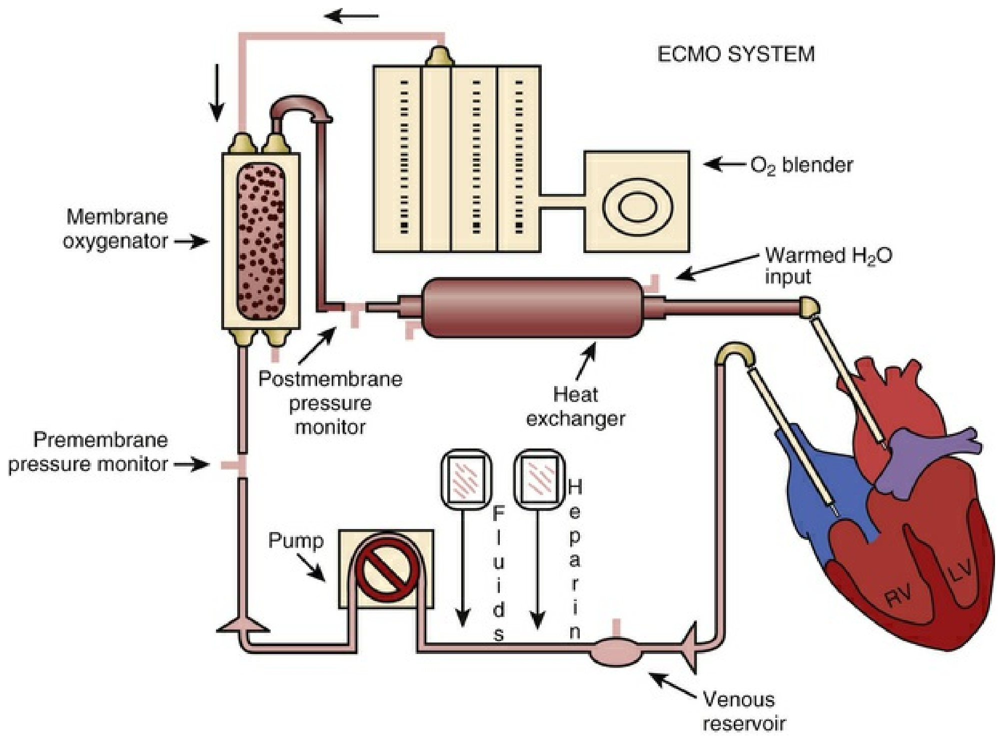

FIG. 30.2 Extracorporeal membrane oxygenation circuit.

Venoarterial (V-A) ECLS provides biventricular and pulmonary support. It is important to note that complete cardiac bypass cannot be provided by V-A ECLS due to incomplete capture of the venous return by the venous cannula. Routine cannulation for V-A ECLS occurs via one of three vascular access points: The transcervical approach places the venous cannula in the right atrium (RA) via the right internal jugular vein and the arterial cannula in the transverse aortic arch via the right carotid artery; the transthoracic approach results in direct cannulation of the RA and ascending aorta through a median sternotomy for patients who either cannot be weaned from cardiopulmonary bypass or require MCS in the immediate postoperative period; and the femoral artery and vein cannulation for adolescents and adults, which utilizes longer cannulae to reach the RA and descending aorta. A combination of these approaches with more than one venous cannulation site can be employed when very high flows are required. The transcervical and transthoracic approaches are the preferred methods for small children. Fig. 30.3 demonstrates a chest radiograph obtained for evaluation of cannula placement in a patient supported by V-A ECLS. Venovenous (V-V) ECLS provides pulmonary support without cardiac support. In V-V ECLS a single double-lumen cannula is placed in the RA through a transcervical approach. This cannula provides both inflow and outflow for the circuit. V-V ECLS can improve right ventricular (RV) function as a result of oxygenated, pH-balanced blood flowing to the lungs, thus decreasing pulmonary vascular resistance (PVR) and right heart afterload.

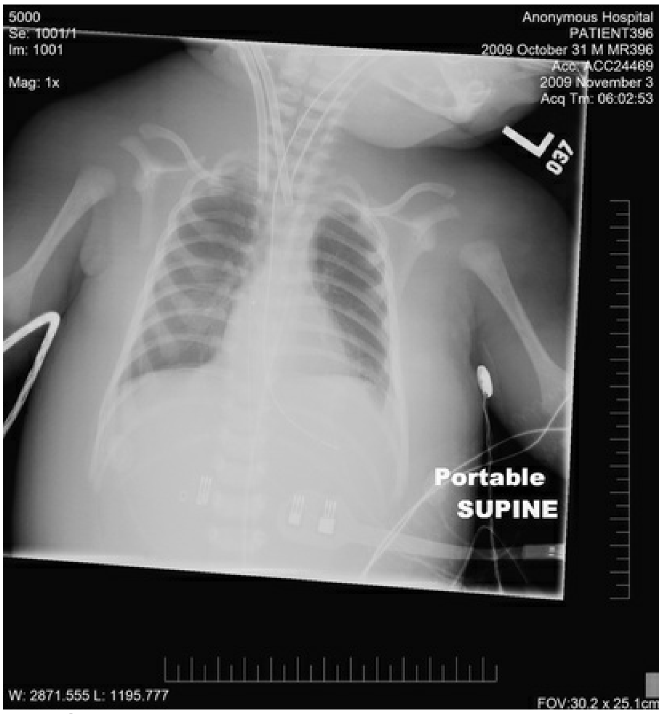

FIG. 30.3 Chest radiograph showing extracorporeal membrane oxygenation cannulas.

Although some patients experience improvement in overall cardiac function with V-V ECLS, this might not be sufficient or sustained. Therefore when ECLS is necessary for significant myocardial dysfunction, V-A ECLS is the preferred modality. See Table 30.3 for comparison of V-A versus V-V ECLS.

TABLE 30.3

Venoarterial Versus Venovenous Extracorporeal Membrane Oxygenation

	VV ECMO	VA ECMO
Organ support	Pulmonary	Pulmonary and cardiac
Cannulation site	Transcervical or femoral	Transcervical, transthoracic, or femoral
Pump	Roller or centrifugal	Roller or centrifugal
Length of support	Days to weeks	Days to weeks

Prior to pediatric VAD technology, the *No Membrane Oxygenator Ventricular Assist Device (NOMO-VAD)* was an adaptation of traditional ECLS whereby the oxygenator was omitted and the circuit shortened. This technique allows for MCS without the pulmonary support of ECLS, thus limiting some of the harmful inflammatory effects from exposure to the oxygenator and reducing the need for anticoagulation. It has been utilized successfully in neonates following first-stage palliation of hypoplastic left heart syndrome.[48,49]

Extracorporeal Membrane Oxygenation Indications and Contraindications

It is widely accepted that all patients considered for MCS should have either a reversible physiologic process or be a candidate for bridge to transplant or destination therapy. The time frame in which recovery is expected and the severity

of cardiac or other organ failure are used to guide optimal device selection. Several studies emphasize that the importance of early institution of ECLS before a prolonged period of low cardiac output results in multiorgan dysfunction. Appropriate patient selection is vital to maximize survival.[50-52]

Myocarditis

The clinical course of myocarditis is variable with some patients presenting with subclinical disease and others with an indolent course progressing to a dilated cardiomyopathy, whereas a distinct subset presents with fulminant disease. Without MCS, these patients with rapidly progressive disease had expected survival rates of only 25% to 50%. With aggressive utilization of ECLS as bridge to transplantation or recovery, survival rates for patients are now reported as high as 90%.[53,54] It has been shown that the institution of MCS can normalize ventricular geometry, cellular composition, metabolism, and ultimately function, a phenomenon referred to as reverse remodeling. This process is thought to improve ventricular dysfunction because of favorable influences on the neurohormonal cardiovascular milieu and ventricular unloading.[55] For patients with end-stage dilated cardiomyopathy secondary to myocarditis, the use of MCS without transplantation has resulted in survival rates as high as 67% to 80%.

Postcardiopulmonary Bypass

Failure to wean from cardiopulmonary bypass occurs in approximately 1% to 3.2% of pediatric congenital cardiac surgery cases.[56,57] Individual institutions have reported survival rates to hospital discharge between 32% and 54% for pediatric patients who require MCS after cardiac surgery. One small series has reported a survival rate as high as 80%.[58] However, the July 2015 Extracorporeal Life Support Organization (ELSO) registry report for postoperative cardiac surgery patients younger than 16 years of age noted an overall survival rate of only 47%. The use of MCS is currently widely accepted to support vital organs while allowing for myocardial recovery. It is imperative that these patients be evaluated for the presence of residual cardiac defects that may be causing or worsening cardiovascular collapse. Intraoperative transesophageal echocardiography (TEE), transthoracic echocardiography (TTE), and diagnostic cardiac catheterization may identify the need for reoperation or interventional cardiac catheterization to improve the patient's hemodynamic status.[59] Balloon valvuloplasty, angioplasty of aortic arch obstructions, device closure of residual septal defects, coil occlusion of aortopulmonary collateral vessels, or atrial septostomy all may be crucial interventions to improve the patient's hemodynamic state and allow for separation from MCS. Untreated and significant residual cardiac defects have been shown to be almost universally fatal for patients requiring MCS. The use of MCS for postcardiotomy support in neonates and infants with single ventricle physiology is technically more complex with worse outcomes, and thus it is considered a relative contraindication to MCS at some centers.[60] The 2015 ELSO report lists a 33% survival rate for ECLS use in patients following the stage I Norwood procedure, lower than for other postcardiotomy patients and falling to 19% if hemodialysis is required (Extracorporeal Life Support Organization: ECLS Registry Report. International

Summary. Ann Arbor, MI, Extracorporeal Life Support Organization, 2015).

Extracorporeal Cardiopulmonary Resuscitation

In-hospital cardiac arrest in children continues to be associated with dismal outcomes despite advances in cardiopulmonary resuscitation (CPR). A prospective multicenter observational study from the National Registry of Cardiopulmonary Resuscitation reported a survival rate to hospital discharge of 27%, although a good neurologic outcome for 73% of survivors was seen.[61,62] A multicenter observational study from the Pediatric Emergency Care Applied Research Network (PECARN) reviewed in-hospital cardiac arrests that occurred during an 18-month period between 2003 and 2004 in which extracorporeal cardiopulmonary resuscitation (ECPR) was available. In this cohort, 49% survived to hospital discharge with the utilization of ECPR with a good neurologic outcome for 76% of survivors. Both studies excluded out-of-hospital, do-not-resuscitate, or neonatal intensive care unit patients. However, although neurocognitive outcome has improved for survivors of cardiac arrest, the duration of CPR remains inversely proportional to survival. One center demonstrated that a witnessed in-hospital cardiac arrest of >30 minutes in duration was universally fatal without the utilization of ECPR.[63] This result has led to an emerging interest in the use of ECPR for patients who failed to quickly reestablish a perfusing rhythm and adequate circulation with conventional CPR. The American Heart Association guidelines for in-hospital pediatric cardiac arrest now recommend consideration of MCS during cardiopulmonary resuscitation if the conditions leading to the arrest are likely to be reversible or amenable to heart transplantation. However, wide variability in patient selection and the ability to institute MCS in a timely fashion (ideally <60 minutes) has led to variable success with survival rates ranging from 0% to 100%.[64,65] Thus some large centers have created systems for rapid deployment ECLS utilizing a team that is immediately available to cannulate with a preprimed circuit. The 2015 ELSO Registry for neonatal and pediatric patients supported with ECLS following cardiac arrest reported a survival to hospital discharge of 38%.

Bridge to Transplantation

Although heart transplantation is the treatment of choice for end-stage myocardial failure, many children die every year waiting for a suitable organ to become available. As a result, MCS is now increasingly utilized as a bridge to heart transplantation. The most common indications for MCS as a bridge to transplant include cardiac failure due to congenital heart disease, cardiomyopathy, and graft rejection after heart transplantation.[66,67] Children with myocardial failure secondary to myocarditis also demonstrate increased short-term survival when treated with MCS and transplantation.[68]

Complications associated with ECLS generally limit the duration of support to approximately 2 weeks, but as long as complications precluding transplant have not developed, no arbitrary cutoff for duration of ECLS should be determined. A review of the United Network for Organ Sharing (UNOS) database from 1995 to 2005 evaluated both clinical status at transplantation and risk factors for the short- and long-term mortality of patients supported with various MCS devices. This study

revealed that 30-day survival was significantly decreased for patients bridged to transplant with ECLS versus VAD, although long-term (10-year) survival was not affected. Not surprisingly, preoperative severity of illness predicted early survival following transplantation. The overall 10-year survival was 56.8% in patients supported with MCS prior to transplantation.[69]

Malignant Dysrhythmias

MCS can be lifesaving for pediatric patients with malignant dysrhythmias unresponsive to pharmacotherapy. A subset of patients with acute fulminant myocarditis will present with refractory LCOS and ventricular tachycardia or high degree heart block that further compromises end-organ perfusion. In this scenario, MCS may be used to bridge patients to recovery or transplantation. Several potentially lethal arrhythmias such as supraventricular tachycardia, junctional ectopic tachycardia, ventricular tachycardia, or torsades de pointes can occur congenitally, become acquired in the perioperative period, or manifest as a result of the ingestion of toxic substances or medications.[62,70] Again, ECLS can allow time for resolution of dysrhythmia with aggressive medical treatment and the subsequent recovery of cardiac function.

Refractory Respiratory Failure

Respiratory failure refractory to maximal medical therapy is the most common indication for ECLS in neonates. Causes include meconium aspiration syndrome, congenital diaphragmatic hernia, persistent pulmonary hypertension of the newborn, sepsis, or other congenital lung abnormalities. The first to perform a systematic comparison of neonatal ECLS practice patterns and respiratory failure deaths between countries demonstrated distinct differences between the United States (US) and the United Kingdom (UK). It concluded that US clinicians seem more willing to utilize ECLS for persistent pulmonary hypertension of the newborn and congenital diaphragmatic hernia. This difference in practice pattern was correlated with a decrease in the US neonatal death rate from congenital diaphragmatic hernia in comparison to the UK.

The most common diagnosis in the pediatric respiratory ECLS group of patients is acute respiratory distress syndrome (ARDS). Overall survival for this group of patients remains at 56%. The duration of ECLS is often longer for respiratory failure than cardiac failure. ECLS for respiratory failure is discussed in detail in Chapter 59.

Other Indications

Since the 1990s, successful treatment of pediatric patients with ECLS has increasingly being described in individuals that would have been excluded in the past, such as patients with trauma, immunosuppression, bleeding diatheses, sickle cell disease, status asthmaticus, septic shock, pulmonary embolism, established multiple organ system failure, among others.

Contraindications

Although individual institutions may have variations to this list, there are only a few

absolute contraindications to ECLS, including irreversible cardiac failure without the option for transplantation, irreversible lung failure, severe neurologic dysfunction, grade III/IV intracranial hemorrhage, uncontrolled bleeding, and congenital anomalies/genetic syndromes with short expected life spans. Relative contraindications include prematurity (<34 weeks), weight <2 kg, grade II intraventricular hemorrhage, and recent bleeding.[71] Cardiac arrest is not a contraindication if rapid effective CPR was initiated, the underlying etiology is deemed reversible, and time for cannulation is <60 minutes. The challenge remains determining what is *irreversible, shortened life span, poor prognosis,* or *severe,* as these definitions have changed over time and with differing expectations for quality of life if survival is attained. Technical limitations are an inability to obtain vascular access secondary to thrombosis, abnormal anatomy, or prior surgery.

Critical Care Management During Extracorporeal Life Support

Patients who require MCS are by definition critically ill, often with multiple end-organ dysfunction, and thus it is not surprising that complications occur with a greater frequency for this group of patients than for other critically ill patients. The basic management principles are discussed in this section. Table 30.4 summarizes the most common reported complications for pediatric patients supported by ECLS.

TABLE 30.4

Complications of Extracorporeal Membrane Oxygenation, Extracorporeal Life Support Organization Registry, July 2015

% Reported	Respiratory Runs: Neonatal N = 23,495	Respiratory Runs: Pediatric N = 4263	Cardiac Runs: 0 to 30 Days N = 3980	Cardiac Runs: 31 Days to 1 Year N = 2,527	Cardiac Runs: 1-16 Years N = 2131
Raceway rupture	0.3%	0.7%	0.3%	0.7%	0.8%
Oxygenator failure	5.9%	13.3%	7.5%	8.4%	9.2%
Pump malfunction	1.7%	2.8%	1.6%	2.1%	2.3%
Seizures	9.9%	6.2%	7.8%	9.6%	5.2%
CNS infarct	7.8%	3.8%	3.6%	3.9%	4.1%
CNS hemorrhage	6.7%	5.7%	11.3%	5.2%	3.2%
Brain death	1%	5.7%	1.2%	3.9%	7.9%
Hypertension	12.6%	15.3%	8.2%	11.5%	10.8%
CPR	2.3%	5.8%	3.4%	3.1%	4.3%
Cardiac stun	5.1%	1.6%	6.9%	5%	5.5%
Tamponade	0.6%	2.2%	6.4%	5.7%	5.6%
Cannulation site bleeding	6.9%	14.4%	9.8%	10.6%	16.1%
Surgical site bleeding	6.2%	14.7%	32%	34.5%	30%
Gastrointestinal hemorrhage	1.7%	4.2%	1%	2%	2.9%
Infection	6.1%	18.9%	7.8%	12.6%	11.4%
Hemofiltration	14.3%	20.1%	25.6%	21.1%	18.8%
Continuous arteriovenous hemodialysis	1.4%	6.2%	5.6%	4.5%	6.1%
Dialysis	3.3%	14.5%	11%	12.5%	13.3%

Cardiac Output

When assessing the hemodynamic state of a patient, one must consider to what

degree conventional support (ie, mechanical ventilation and vasoactive agents) is contributing to cardiac and pulmonary function versus the ECLS system. The amount of flow provided by the ECLS system is measured through ultrasonic flow probes on the high-pressure side of the circuit beyond where any shunts (ie, high-pressure to low-pressure connection through a hemofilter) may occur. An approximation of flow generated by the pump can be calculated from the product of the revolutions per minute (RPMs) and circuit tubing diameter. For most cardiac ECLS patients, flow is initiated at 120 to 150 mL/kg/min. However, it is important to note that flow should be adjusted to fit the physiologic needs of each patient. Patients with septic shock may require higher flows approaching 200 mL/kg/min to support their metabolic needs, assuming venous drainage is sufficient to yield such flows. A precise measurement of the patient's intrinsic cardiac output (ie, the amount of blood that is not bypassed through the ECLS circuit) is often unobtainable. However, indirect evaluation of the patient's cardiac output is possible through an assessment of arterial systolic blood pressure, pulse pressure, heart rate, organ perfusion, mixed venous oxygen saturation, and lactic acid levels on a given flow rate. Comparisons of these variables over time allow the clinician to make decisions regarding the adequacy of circulatory support or the readiness to wean from support. An echocardiogram can also provide valuable information about cardiac filling and function and guide therapy, particularly when weaning from ECLS or during a trial off ECLS. Mixed venous oxygen saturation (SvO_2) is measured in the venous return portion of the circuit, with a goal of 65% to 80%. However, if a left-to-right shunt exists such as a left atrial vent, the mixed venous saturation will be falsely elevated, particularly if the patient is receiving high FiO_2 and PEEP. Serial lactate measurements are often helpful to aid in the assessment of global end-organ perfusion. Elevated lactate levels may occur in patients with ongoing hepatic dysfunction, sepsis, low cardiac output, and end-organ hypoperfusion. A rough approximation of the relative contributions of the patient and circuit pulmonary parameters is possible by analyzing serial patient and circuit blood gas assays (pH, $paCO_2$, paO_2, SaO_2) while taking into consideration the mechanical ventilation settings (including FiO_2 and PEEP), circuit flow rate, gas sweep rate, and circuit oxygen concentration. Finally, *shunts* within the patient or the circuit must be taken into consideration. An example of a right-to-left patient shunt includes a patient with a patent ductus arteriosus, atrial septal defect, or ventricular septal defect in the setting of severe pulmonary artery hypertension. Circuit left-to-right shunts are generally limited to a left atrial *vent, open bridge,* the A-V hemodialysis filter, and in vivo continuous arterial blood gas device. Total blood flow for the patient on MCS requires the addition of ECLS circuit flow with the patient's native cardiac output minus any *shunt* within the system as a whole.

Troubleshooting

Hemodynamic compromise often continues despite MCS, and low-dose inotropes or inodilators can aid cardiac contractility to augment native cardiac output and reduce afterload to both the right and left ventricles. The most commonly utilized agents are dopamine (3–5 μg/kg/min), epinephrine (0.03–0.05 μg/kg/min), dobutamine (5 μg/kg/min), or milrinone (0.25–0.75 μg/kg/min). The use of catecholamines in high doses is detrimental to cardiac recovery and should be avoided by increasing circuit

flow to provide adequate circulation. Tachydysrhythmias and pulseless electrical activity requiring cardiopulmonary resuscitation occurs in 3% of neonatal and pediatric ECMO runs (see Table 30.4). Chemical/electrical cardioversion of any dysrhythmia should be attempted quickly to promote recovery of cardiac function. Cardiac pacing can be utilized to optimize cardiac output.

Hypovolemia

Hypovolemia is a common occurrence during MCS for a variety of reasons. Inadequate venous drainage secondary to cannula malposition, cardiac tamponade, tension pneumothorax, or hemothorax may occur and generally results in hypotension requiring immediate correction (see Table 30.4). Ongoing evaporative losses from the oxygenator and bleeding secondary to coagulopathy can contribute to hypovolemia. Initiation of ECLS activates a host of inflammatory mediators resulting in capillary leak and hypovolemia.[72] Finally, attempts at mobilizing the large amount of *third spaced* fluid with either diuretics, hemofiltration, or through drains in pleural/peritoneal cavities can quickly cause either inadequate cardiac output from the patient or inadequate venous drainage to the ECLS circuit.

Hypertension

Hypertension secondary to neurohormonal dysregulation is one of the most common and unavoidable cardiovascular complications of ECLS (see Table 30.4). Although hypertension has not been demonstrated to negatively impact patient survival, its presence can worsen bleeding or further impair cardiac function and thus should be promptly adressed.[73]

Cardiac Stun

Cardiac stun, a term that describes reversible global dyskinesia of the ventricle, was coined by Braunwauld and Kloner in 1982.[74,75] Reversible cardiac dysfunction that results in the lack of antegrade left ventricular ejection during systole resembles electromechanical dissociation, which has been observed frequently in patients following the initiation of V-A ECLS. Excluding conditions of physiologic tamponade from thoracic tissues, blood, or air, an infant on ECLS should have sufficient cardiac function to generate a minimal pulse pressure of 10 mm Hg. Evaluations of patients who experience cardiac stun upon initiation of ECLS defined this condition as the absence of aortic valve opening during systole, equalizing of the patient preductal and postmembrane circuit PaO_2, and absence of pulse pressure in the aorta. The etiology of cardiac stun is multifactorial and hypothesized to be the sequelae of acute ischemia followed by reperfusion or severe electrolyte disturbances. The incidence of stun on ECLS is 5% to 12% in neonates and, when present and prolonged (>24 hours), results in a significant increase in mortality for these patients (see Table 30.4). Stun typically occurs during the initiation of bypass in patients who were more hypoxic, hypercarbic, acidotic, and suffered a cardiac arrest prior to ECLS. Important factors in trying to minimize cardiac stun upon the initiation of ECLS include correcting the pH and ionized calcium levels in the circuit and infusing calcium chloride to the patient upon commencing ECLS, followed by close monitoring of arterial blood gases and electrolytes with rapid correction of abnormalities.

Echocardiography and Cardiac Catheterization

Initial diagnostic and hemodynamic assessment should be attempted by transthoracic echocardiography, but imaging windows may be severely limited resulting in insufficient information. Transesophageal echocardiography (TEE) may improve diagnostic accuracy but may not be possible secondary to bleeding risks or patient size. Even if adequate imaging is obtained, the specific hemodynamic state of the patient on ECLS must be taken into account when interpreting these studies. Invariably, the loading conditions of the heart are markedly altered during ECLS. The echocardiographer should actively interface with the ECLS team (to potentially modify flows, add volume, increase mechanical ventilator support, etc.) in order to obtain the most comprehensive assessment of cardiac function to inform clinical decisions regarding the continuation or removal of further ECLS support. Cardiac catheterization can be a useful tool for select patients who fail to wean from ECLS. The specific loading conditions of the heart must be considered in the context of the acquired data in order to make sound clinical decisions. Therapeutic interventions that might be performed in the catheterization lab include balloon or blade atrial septostomy to alleviate left atrial hypertension, balloon valvuloplasty or angioplasty of vascular obstructions, device closure of residual atrial or ventricular shunts, and coil embolization of aortopulmonary shunts.[76] Correction of these types of residual defects in the catheterization laboratory or surgical correction in the operating room may be required to allow for separation from MCS. In a review of 216 courses of ECLS for pediatric patients, 50 of 60 catheterizations performed led to an intervention either during or after the catheterization procedure.[77] Complications of the catheterization included myocardial perforation in two infants, each weighing less than 3.5 kg. Both were treated for the complication and survived the procedure.[77] For patients with significant left ventricular failure, it may be necessary to decompress the left heart to prevent or reverse pulmonary edema or hemorrhage, decrease mitral regurgitation, and, importantly, improve coronary perfusion to increase the chances of myocardial recovery. In this scenario, *venting* of the left ventricle occurs through placement of a cannula in the left atrial appendage connected to the venous drainage to the ECLS circuit. This is accomplished in the operating room during transthoracic ECLS cannulation or in the catheterization laboratory through creation of an interatrial connection via balloon or blade septostomy. This procedure can markedly improve left ventricular function and increase the chances of survival.[78,79]

Single Ventricle

Lower survival rates are universally found in this subset of patients, which may be attributed to an imbalance of the systemic and pulmonary circulations, volume burden to the single ventricle after complex palliative surgery, compromised single ventricle function (particularly with right ventricular morphology), and impaired coronary perfusion to the systemic ventricle when a systemic-to-pulmonary artery connection (eg, modified Blalock-Taussig [BT] shunt) results in diastolic runoff from the aorta. Despite the challenges presented, larger centers continue to report improved outcomes with the accumulation of experience and application of innovative strategies. For example, initial efforts to balance the systemic and pulmonary circulations on ECLS included either completely or partially occluding

the aortopulmonary shunt, which has now been demonstrated to increase mortality. The use of smaller size BT shunts or the use of the Sano modification (RV to PA nonvalved conduit for stage one hypoplastic left heart palliation) has contributed to decreasing the recirculation that would otherwise occur. Of note, higher ECLS with flows approaching 200 mL/kg/min may be required to provide adequate systemic and pulmonary support when the shunt is left open.[80,81]

Anticoagulation Strategies

ECLS requires meticulous management of hemostasis to limit patient morbidities. Hemorrhagic and thrombotic complications are a major concern for patients during ECLS, particularly after cardiac surgery. Bleeding can manifest at surgical sites (arterial/venous cannulation sites, surgical repair sites (atriotomy, ventriculotomy, aortotomy sites, sternal incision, indwelling catheter sites, etc.) or masked in areas such as the thorax, intracranial vault, or the gastrointestinal tract (see Table 30.4). Prevention strategies that target reduction of hematologic complications focus on maintenance of the hemostatic regulatory mechanisms as close to normal as possible.[82-85] Apart from single-center experience, no well-defined consensus or protocol is available for pediatric and neonatal ECLS. The patient's age, diagnosis, clinical status in conjunction with the specific details of the ECLS device, and, finally, the flow through the circuit will dictate which anticoagulation strategy should be employed. The most commonly utilized agent for anticoagulation on ECLS is continuously infused unfractionated heparin. Most centers measure platelet counts, hematocrit, prothrombin time (PT), partial thromboplastin time (PTT), fibrinogen, specific factor levels (ie, anti-Factor Xa, antithrombin III), quantitative heparin levels, and activated clotting time (ACT). The ACT is the most commonly measured test for coagulation, as it can be performed quickly at the bedside, though other coagulation tests are available as point-of-care tests (ie, PTT).[86,87] Despite this advantage, ACT results vary markedly based on the technique used, and it is a nonspecific measure of coagulation because it measures the total time for a clot to form after ex vivo activation. The ACT is a global composite of the different individual components of coagulation, and thus more specific tests (listed above) must be used in concert to ascertain which specific component in the coagulation cascade is affected. Thus no single test is currently used to guide the anticoagulation regimen, but rather a panel of tests must be obtained and analyzed in concert. Several centers have reported on the effective use of thromboelastography (TEG) in determining patient coagulation status.[88] When “adequately anticoagulated on a continuous unfractionated heparin infusion,” the goal ACT should be between 180 and 220 seconds when the ECLS pump is flowing at full flow (ie, >150 cc/kg/min). This goal can be decreased to 160 seconds on full flow if significant bleeding is present, particularly in the immediate postoperative period. Unfractionated heparin is metabolized via two mechanisms: at low doses, via a saturable mechanism representing clearance by the reticuloendothelial system and endothelial cells to which heparin binds with high affinity, and at high doses, via a nonsaturable mechanism represented by renal excretion. Thus close monitoring during ECLS must be followed when a patient's urinary output is oscillating between oliguria and polyuria.

Newer treatment strategies include the use of additional agents such as antithrombin III (ATIII) in either bolus or infusion form to correct abnormalities in the clotting cascade. ATIII is an alpha2-glycoprotein serine protease inhibitor that

inactivates a number of enzymes from the coagulation system including the activated forms of factors II, VII, IX, X, XI, and XII. Replacement of ATIII is indicated when its level is low (<30%) and heparin infusion rates are increasing without a concomitant increase in ACT or PTT.[40,89,90] Anticoagulation with Coumadin, clopidogrel, low-molecular-weight heparin, and aspirin individually or in combination can be considered with certain MCS devices other than ECLS.[91]

Heparin-induced thrombocytopenia (HIT) is a relatively rare but serious complication of heparin administration caused by antibodies binding to a complex of heparin and platelet factor 4 (PF4) that leads to large vessel thrombosis and increased mortality. A drop in platelet count by more than 50% of the highest previous value should raise suspicion of HIT and trigger investigation. Treatment includes discontinuing heparin administration and initiating direct thrombin inhibitor therapy (ie, argatroban) if continued anticoagulation is needed.[82]

The lysine analogs tranexamic acid and epsilon aminocaproic acid are antifibrinolytic agents that have been shown to reduce bleeding in ECLS patients undergoing surgical procedures. However, prophylactic administration failed to reduce the incidence of intracranial hemorrhage in neonates.[86]

Profound abnormalities in many components of the coagulation cascade commonly occur in postoperative cardiac patients on ECLS. With this in mind, an attempt to normalize components of coagulation not impacted by heparin is important. Platelets are consumed at surgical bleeding sites, sequestered by the membrane oxygenator, so transfusions are required to maintain counts greater than $100{,}000/mm^3$. Administration of fresh frozen plasma to broadly increase multiple factor activities is also common. When hypofibrinogenemia occurs, cryoprecipitate infusion can be utilized due to the high concentrations of fibrinogen in the low volume of the cryoprecipitate unit. The availability of plasma protein concentrate (PPC) allows administration of highly concentrated factors in a substantially reduced volume, thus reducing the volume burden associated with conventional therapy. Although rare, the application of heparin-free ECLS has been reported in polytrauma patients.[92]

Ventilation Strategies

Ventilator management during ECLS remains controversial. Although data exist to guide clinicians regarding prevention of barotrauma, volutrauma, and oxygen toxicity for mechanically ventilated patients with acute respiratory distress syndrome in general, consensus lacks for patients on ECLS. Lung collapse strategies used for respiratory support on ECLS are not utilized by most cardiac centers. Goals continue to target the prevention of atelectasis with utilization of appropriate PEEP in order to maximize oxygenation of non-bypassed blood returning to the left atrium, which then is ejected by the left ventricle to perfuse the coronary arteries. In addition, providing modest levels of ventilator support can be achieved with either a pressure- or volume-limited mode of ventilation targeting a delivered tidal volume of 6 to 8 mL/kg. Respiratory rates between 10 and 25 are set depending on the age and *rest* strategy being employed and the degree that the patient's lungs are required for gas exchange. Optimizing PaO_2 to the patient and circuit by blending FiO_2 to keep the FiO_2 <0.6 reduces free radical formation and oxygen toxicity, providing adequate oxygenation to decrease pulmonary hypertension and optimize

myocardial O_2 delivery. Chest radiographs are routinely performed to assess and guide strategies to optimize lung volume so that volutrauma and barotrauma are avoided.

Fluid, Nutrition, and Renal

Fluid overload and electrolyte disturbances such as high or low serum levels of potassium, calcium, magnesium, and phosphorous are common and need correction. Most cardiac patients on ECLS receive total parenteral nutrition due to the increased risk of gastrointestinal complications in patients with cardiac defects, umbilical artery catheters, poor perfusion, or other bowel abnormalities. A select subset may tolerate trophic enteral feedings. Diuretics, commonly furosemide, are often employed to provide optimal fluid balance in patients with significant capillary leak and fluid retention (see Table 30.4). Optimization of fluid status is essential to weaning and eventual separation from ECLS support. For anuric or oliguric patients, early placement of an in-line hemofilter into the ECLS circuit with or without countercurrent dialysate is recommended. However, the management decisions that balance the use and timing of diuretics versus hemofiltration are center specific. The indications for initiation of dialysis are the same as for other critically ill patients with renal failure. Multiple retrospective reviews of patients supported by ECLS have found renal replacement therapy to be a risk factor for increased mortality. No causal relationship has been identified, and further investigation in this area is warranted.[93,94]

Analgesia and Sedation

Adequate analgesia and sedation are essential for both safety and comfort and to decrease metabolic demands in patients with circulatory compromise in the early postoperative recovery period. Typically, an opiate and a benzodiazepine class drug are utilized. Infusions may be utilized with cautious monitoring, as toxicity from propylene glycol and other solvents have been reported with benzodiazepine use.[95] Neuromuscular blockade should largely be avoided to limit critical care myopathy, allow for regular evaluation of the central nervous system, and limit soft tissue fluid accumulation. Central nervous system infarcts, hemorrhage, or seizures are all known complications of ECLS (see Table 30.4). For infants with an open fontanel, a daily head ultrasound should be performed regularly early in the course of treatment and with any change in clinical neurologic status. For older patients, a significant change in their neurologic status has a high likelihood of heralding major intracranial pathology, which needs to be promptly diagnosed by computed tomography in order to guide treatment and determine patient viability.

Several centers have reported a new approach in which patients are supported without the need of continuous analgesia and sedation and without the need of mechanical ventilation. This *awake ECLS* modality has been used as bridge to recovery, bridge to VAD, or bridge to transplantation.[96]

Infection

It is not surprising that patients on ECLS are at a high risk of developing nosocomial bloodstream infections (BSI). Identified risk factors include the duration of ECLS[97] open versus closed chest cannulation, the presence of central venous lines, and

undergoing a major procedure prior to or while on ECLS. It appears that older patients on ECLS for respiratory failure may be at higher risk of health care–associated infection than neonates or cardiac patients (see Table 30.4). Bloodstream infections during ECLS for both pediatric cardiac patients postcardiopulmonary bypass and neonates with cardiac or respiratory failure have been associated with a poor outcome. The diagnosis of sepsis is difficult in patients supported with ECLS. Although variable degrees of leukopenia have been documented for neonates supported with ECLS, an increase in phagocytosis and intracellular killing by neutrophils also occurs. Temperature is controlled by the circuit's heat exchanger, so infection is generally not manifested by fever in these patients. Hypotension or thrombocytopenia may occur for a variety of reasons. In view of this observation, the standard of care in many ECLS centers has been to perform routine surveillance cultures and provide prophylactic antibiotics. However, management strategies to limit infectious risks continue to evolve. Due to lack of a proved benefit and concerns regarding the long-term impact of broad-spectrum antibiotics on local bacterial resistance profiles, an increasing number of centers now perform daily blood cultures without the routine use of prophylactic antibiotics.[98] Additional retrospective data may suggest that routine surveillance cultures may not be warranted.[99] Further investigation is needed to determine the impact of prophylactic antibiotic use on the incidence of BSI, local antimicrobial flora, length of stay, survival, and cost.

Intrahospital Transport

Crucial situations exist for patients supported with ECLS that require intrahospital transport. This can include mobilization from the intensive care unit to a variety of locations such as the catheterization laboratory, radiology, or the operating suite. Reluctance to perform diagnostic or therapeutic interventions is often driven by fear of potentially disastrous complications during transport. These fears are largely unfounded. Guidelines designed to promote the establishment of an organized, efficient transport process supported by appropriate equipment and personnel have been recognized and are increasingly utilized in hospitals. Intrahospital transport for patients on ECLS is a labor-intensive process that should be approached in a coordinated effort with specific focus on the preparatory phase, the transfer phase, and the posttransport phase. However, with careful attention to these aspects, centers have demonstrated that intrahospital transport for patients on ECLS can be carried out safely and without major complications.[100]

Ventricular Assist Devices

The two main types of VADs are pulsatile pumps and continuous flow pumps. Continuous flow pumps have been preferred worldwide because of their smaller size and high performance. Based on the pump-patient interface, devices can be classified as intracorporeal, extracorporeal, or paracorporeal. Most VADS share similar basic principles. Cannulation depends on the type of support required. The right atrium (venous drainage) and pulmonary artery (arterial return) are cannulated for right ventricular assist device (RVAD), and the left atrium (venous drainage) and aorta (arterial return) are cannulated for left ventricular assist device

(LVAD). A combination of both right and left ventricular assist devices is termed biventricular assist device (BiVAD). The pump is connected to a controller and power supply. Pumps have differences in modes of operation, size, and placement. A comparison of ECLS and VAD support is listed in Table 30.5.

TABLE 30.5

Extracorporeal Life Support Versus Ventricular Assist Devices

	ECLS	Centrifugal VAD	Pulsatile VAD
Oxygenator	Yes	No but can be added	No
Anticoagulation	ACT 180-200	ACT 160-180	Aspirin/warfarin/LMWH
Support	Cardiac + respiratory	Cardiac + respiratory	Cardiac
Type of ventricular support	Biventricular	Uni or biventricular	Uni or biventricular
Ventricular decompression	May need LA "venting"	Via direct drainage cannula in LA or LV apex	Via direct drainage cannula in LV apex
Risk of air embolus	Low	Yes (especially with LVAD)	Yes (especially with LVAD)
Length of support	Short term	Short term	Long term
Cannulation site	Transthoracic or transcervical	Transthoracic	Transthoracic

ACT, activated clotting time; *LA*, left atrial; *LMWH*, low-molecular-weight heparin; *LV*, left ventricular; *LVAD*, left ventricular assist device.

Pulsatile VADs are devices that function on the principle of "positive displacement" by trapping a fixed amount of blood then forcing (displacing) that trapped volume into an exit cannula. Since the early report of pneumatically driven, pulsatile, paracorporeal VADs in children, the pediatric experience with pulsatile devices has continued to grow.[101,102] Advantages of these devices include the ability to provide long-term (weeks to months) biventricular support without an oxygenator, patient mobility out of the intensive care setting, need for low-level anticoagulation (heparin or warfarin with antiplatelet therapy), and, lastly, the pulsatile nature of flow. Disadvantages include a propensity for thromboembolic complications, high cost when compared to centrifugal VADs, and the need for exteriorization of the cannulae. Infection is also a serious complication, though immobilization of the cannulas close to the exit site can decrease its incidence. Only the paracorporeal Berlin Heart Excor and the Medos HIA (MEDOS Medizintechnik AG, Stolberg, Germany) pulsatile systems have been successfully deployed in children of all ages and as small as 2 kg. These devices have a special silicone system that connects the blood pump to the body. The cannulas are anastomosed to the right atrium and pulmonary artery for right ventricular assist (RVAD), to the apex of the left ventricle (or more rarely to the left atrium) and the ascending aorta for left ventricular assist (LVAD), or both (BiVAD).[103,104] Most times, LVAD insertion may be sufficient for bridging patients to heart transplantation, even in the presence of significant preoperative right ventricular dysfunction. Adequate unloading of the left ventricle reduces the left ventricular end-diastolic pressure and, in turn, reduces right ventricular afterload, which may improve RV systolic function.

The Berlin Heart EXCOR (Berlin Heart AG, Berlin, Germany) is the only labeled VAD available for long-term support of neonates and infants. This is a second-generation, paracorporeal pulsatile pneumatic pump with polyurethane valves and a transparent chamber through which the adequacy of filling and emptying can be assessed and evaluated for thrombus formation. This pump can be used to support left, right, or both ventricles. The blood-contacting surfaces of the pump are heparin
